1 The Reliability and Validity of a Clinical Assessment Tool to Measure Scapular Motion in All  
2 Three Anatomical Planes

3

4

5 **Context:** A single clinical assessment device that objectively measures scapular motion in each  
6 anatomical plane is not currently available. The development of a novel electric goniometer  
7 affords the ability to quantify scapular motion in all three anatomical planes.

8 **Objective:** Investigate the reliability and validity of an electric goniometer to measure scapular  
9 motion in each anatomical plane during arm elevation.

10 **Design:** Cross-sectional.

11 **Setting:** Laboratory setting.

12 **Patients or Other Participants:** Sixty participants (29 females, 31 males) were recruited from  
13 the general population.

14 **Intervention(s):** An electric goniometer was used to record clinical measurements of scapular  
15 position at rest and total arc of motion (excursion) during active arm elevation in two testing  
16 sessions separated by several days. Measurements were recorded independently by two  
17 examiners. In one session, scapular motion was recorded simultaneously with a 14-camera  
18 three-dimensional optical motion capture system.

19 **Main Outcome Measures:** Reliability analysis included examination of clinical measurements  
20 for scapular position at rest and excursion during each condition. Both the intra-rater reliability  
21 between testing sessions and the inter-rater reliability recorded within the same session were  
22 assessed using Intraclass Correlation Coefficients (ICC<sub>2,3</sub>). The criterion-validity was examined by

23 comparing the mean excursion values of each condition recorded by the electric goniometer to  
24 the 3D optical motion capture system. Validity was assessed by evaluating the average  
25 difference and root mean square error (RMSE).

26 **Results:** The between session intra-rater reliability was moderate to good (ICC<sub>2,3</sub>: 0.628-0.874).  
27 The within session inter-rater reliability was moderate to excellent (ICC<sub>2,3</sub>: 0.545-0.912). The  
28 average difference between the electric goniometer and 3D optical motion capture system  
29 ranged from -7° to 4° and the RMSE was between 7-10°.

30 **Conclusions:** The reliability of scapular measurements is best when a standard operating  
31 procedure is used. The electric goniometer provides an accurate measurement of scapular  
32 excursions in all three anatomical planes during arm elevation.

33 **Key words:** Scapula, reliability, validity, measurement, shoulder

34 **Abstract word count:** 299 words

35 **Manuscript word count:** 3577 words

36 **Key Points:**

- 37 • This electric goniometer provides clinicians and researchers with a simple tool to  
38 objectively measure scapular position and motion in all three anatomical planes.
- 39 • There was moderate to excellent intra-rater and inter-rater reliability for measuring  
40 scapular rest position and total excursion within and between testing sessions using the  
41 electric goniometer.
- 42 • The electric goniometer proved to be a valid device to measure scapular motion in the  
43 transverse plane.

44

45 Motion of the shoulder complex consists of a combination of movement from the  
46 glenohumeral, acromioclavicular, and sternoclavicular joints, as well as the scapulothoracic  
47 articulation.<sup>1,2</sup> Moving in multiple anatomical planes during humeral motion, scapula motion is  
48 integral to provide optimal function to the upper extremity.<sup>1-3</sup> Alterations in scapular motion  
49 have been attributed to pathologies such as multi-directional instability, impingement, nerve  
50 palsies, rotator cuff tears, and biceps tendinopathy.<sup>4-6</sup>

51 In order to understand how scapular motion contributes to upper extremity function,  
52 clinicians must be able to accurately quantify scapular motion. Currently, the gold-standard for  
53 evaluating multiplanar scapular motion includes bone pins, radiography, and magnetic  
54 resonance imaging.<sup>2,7-9</sup> Non-invasive reference-standards for tracking scapular kinematics such  
55 as video-based three-dimensional (3D) motion analysis and 3D electromagnetic tracking have  
56 been validated to the gold-standard methods.<sup>8,10</sup> Though proven to be accurate for measuring  
57 scapular motion, these techniques have their drawbacks such as the lack of availability to  
58 clinicians, invasive nature, complex computation, expense, and restriction to a laboratory  
59 setting.

60 To overcome the limitations of laboratory-based methods highlighted above, clinical  
61 assessment techniques are necessary to measure scapular motion in the clinical setting.  
62 Further, reliable and precise objective scapular measurement can guide treatment plans and  
63 rehabilitation efforts of upper extremity pathologies. The objective assessment of scapular  
64 motion has been examined in previous literature.<sup>11-14</sup> Both observation and palpation-based  
65 techniques have been examined, however, the observational approach lacks objective  
66 measurement values, thus rendering the method as a subjective screening tool.<sup>11</sup> The gravity-

67 referenced digital inclinometer, first investigated by Johnson et al.,<sup>13</sup> demonstrated good to  
68 excellent intra-rater reliability (ICC<sub>3,1</sub>: 0.89-0.96) and moderate to good validity ( $r= 0.59-0.73$ )  
69 for measuring the scapular motions of upward and downward rotation in the frontal plane  
70 during arm elevation.<sup>15</sup> Subsequent research by Scibek and Carcia<sup>14</sup> further investigated the  
71 gravity-referenced digital inclinometer to measure the scapular motions of anterior and  
72 posterior tilt in the sagittal plane during arm elevation and reported excellent intra-rater  
73 reliability (ICC<sub>3,1</sub>: 0.97-0.99) and moderate to good excellent validity ( $r= 0.63-0.86$ ).<sup>15</sup> These  
74 findings, supported by subsequent studies, serves as grounds to demonstrate the use of  
75 gravity-referenced digital inclinometers as reliable and valid for measuring scapular motion in  
76 the frontal and sagittal planes.<sup>13,14,16-19</sup>

77 While a digital inclinometer is a non-invasive and portable clinical assessment tool to  
78 objectively measure scapular motion in the frontal and sagittal plane, it is not capable of  
79 measuring the scapular motions of internal and external rotation in the transverse plane due to  
80 their reliance on gravity-referenced sensors. However, new advancements in the development  
81 of a novel electric goniometer, equipped with an inertial measurement unit (IMU), affords the  
82 ability to clinically measure scapular motion in the transverse plane. Similar to the angular  
83 rotation recorded by the accelerometer internal to the gravity-referenced inclinometer, the  
84 IMU captures angular rotations relative to a reference position created and stored by a tri-axial  
85 gyroscope and magnetometer. The additional two sensors allow the system to calculate angular  
86 rotations relative to any defined calibration position, which does not have to be in the line of  
87 gravity, therefore overcoming the limitations faced by gravity-referenced inclinometers.

88 Currently, the ability to easily and accurately quantify scapular motion in all three  
89 anatomical planes with a single clinical device is not available. Although, a new electric  
90 goniometer, equipped with an IMU, has the capability to overcome this limitation, we do not  
91 know if this novel device is reliable or valid for measuring scapular motion in each anatomical  
92 plane. Therefore, the purpose of this study was to investigate the reliability and validity of an  
93 IMU-based electric goniometer to measure scapular motion during arm elevation. Reliability  
94 analyses sought to investigate the intra- and inter-rater reliability by examining the reliability  
95 characteristics of measurements across days and between examiners. Validity analyses sought  
96 to establish criterion-validity by comparing the measurements recorded by the electric  
97 goniometer to a validated reference-standard of 3D optical motion capture. We hypothesized  
98 that the measurements recorded from the electric goniometer would not exceed 10° of error  
99 compared to the 3D optical motion capture system, and the intra-rater reliability of each  
100 examiner between two days of testing would exceed an intraclass correlation coefficient (ICC)  
101 value of 0.80 while the inter-rater reliability between two examiners on a single day of testing  
102 would exceed an ICC value of 0.70. Establishing the reliability and validity characteristics of the  
103 electric goniometer will provide critical evidence regarding the utility of these IMU-based  
104 devices to measure scapular motion. If valid and reliable, these types of devices will provide  
105 clinicians with the ability to objectively measure scapular motion in the clinical setting.

106 **Methods:**

107 *Participants:*

108 A sample of convenience generated a total of 67 inquiries from the general population  
109 within [REDACTED]. All volunteers were screened for eligibility based on the inclusion

110 criteria that required participants to: be between 18-99 years of age, willing to attend two  
111 testing sessions separated by at least 24 hours, have the ability to lift their right arm to at least  
112 120° in the scapular plane, and have no current self-reported current medical restrictions  
113 relating to their upper extremity or spine. An *a priori* power analysis conducted using Nquery  
114 V8.1 software (Statistical Solutions, Boston, MA, United States) prior to data collection  
115 indicated a sample size of 60 participants will have 90% power to detect a difference in means  
116 of 3° in scapular motion and minimize chance of creating a type II error.

117 We identified and enrolled 60 participants (29 females, 31 males, mean age: 30 ± 14  
118 years, height: 1.73 ± 0.10 m, mass: 75.32 ± 16.90 kg) who met inclusion criteria. All participants  
119 completed two testing sessions with an average time between sessions being 9 days. All  
120 participants were provided verbal and written descriptions of the study and signed informed  
121 consent forms prior to data collection. This study protocol was approved the University [REDACTED]  
122 [REDACTED] institutional review board (IRB #XXX).

### 123 *Materials:*

124 The EasyAngle electric goniometer (Meloq AB, Stockholm, Sweden) was used to perform  
125 clinical measurements of scapular motion (Figure 1C). Prior to data collection, an upright  
126 homemade PVC pole was placed at 30° anterior to the frontal plane relative to the participant's  
127 sitting location, marking the scapular plane. The participant was instructed to actively raise  
128 their arm with their wrist touching the PVC pole until they reached 120°, confirmed with a  
129 standard goniometer. When the participant reached 120° of arm elevation, a quick-grip mini  
130 bar clamp (Irwin, Huntersville, NC, United States) was used to mark and physically limit 120° of  
131 arm elevation the PVC pole (Figure 2). An I-beam square bubble level (Model #7724, Johnson

132 Level and Tool Manufacturing, Inc, Mequon, WI, United States) was used to calibrate the  
133 electric goniometer for measurements taken in the sagittal plane as described below.

134 Three-dimensional motion capture was recorded with a Nexus 14-camera high-speed  
135 infrared video-based optical motion capture system (Vicon, Oxford, United Kingdom). Raw  
136 marker trajectory data was stored and reconstructed in Vicon Nexus software (Vicon, Oxford,  
137 United Kingdom). Reconstructed kinematic data were exported and analyzed in Visual 3D (v9  
138 Professional, C-Motion, Germantown, MD, USA).

139 *Procedures:*

140 Clinical measurements were recorded with the electric goniometer independently by  
141 each examiner during arm elevation in the frontal, transverse, and sagittal planes. To facilitate  
142 consistency of clinical measurements between examiners, and to accommodate the placement  
143 of retroreflective markers used for 3D optical motion capture, a standard operating procedure  
144 was implemented. Specific to each anatomical plane in which measurement occurred, the  
145 standard operating procedure specified a calibration technique and the specific placement  
146 location for the electric goniometer based on several scapular landmarks. To measure scapular  
147 motion in the frontal plane, the electric goniometer was calibrated to the floor directly beneath  
148 the participant to represent zero degrees. The electric goniometer was placed on the scapular  
149 spine at the location of one third of the distance between the root of the scapular spine and the  
150 posterior acromion angle, as measured and marked with a cloth tape measure (Figure 1A), and  
151 oriented posteriorly (Figure 1B). To measure scapular motion in the transverse plane, the  
152 electric goniometer was calibrated using a perpendicular edge of a floor tile beneath the  
153 participant to represent zero degrees. The electric goniometer was placed at the same location

154 on the scapular spine as described for frontal plane motion but oriented superiorly (Figure 1C).  
155 To record scapular motion in the sagittal plane, the electric goniometer was calibrated to the  
156 vertical I-beam square level to represent zero degrees and placed on the most prominent  
157 portion of the medial scapular border oriented laterally (Figure 1D).

158 All participants began each trial seated in an upright position on a 35-cm tall stool with  
159 their feet flat on the floor. The motion of arm elevation was explained and demonstrated for  
160 the participant. The participant was able to practice the motion several times and ask questions  
161 prior to data collection. To begin each trial, the examiner applied the electric goniometer to the  
162 specified scapular landmark and asked the participant to assume an upright and relaxed sitting  
163 posture. The scapular rest position was recorded and then the participant was prompted to  
164 perform the desired condition. Upon completion of active movement, the participant held their  
165 final position for several seconds while the examiner measured the end scapular position. Total  
166 excursion values were calculated by subtracting the initial scapular position (rest) from the final  
167 scapular position (end) observed upon completion of motion. Three trials of active arm  
168 elevation were recorded for each scapular condition, totaling nine trials of motion for data  
169 collection. A constant pressure and contact were maintained with the scapular landmark during  
170 each movement. The order of anatomical planes was randomized prior to testing and the same  
171 order was used on both days of testing. Clinical measurements of scapular motion were  
172 interpreted following the guidelines set by the International Society of Biomechanics<sup>20</sup> where  
173 positive scapular motion in the frontal, transverse, and sagittal planes occurs as downward  
174 rotation, internal rotation, and posterior tilt, respectively.

175 On one day of testing, 3D optical motion capture was recorded simultaneously as the  
176 clinical measurements. Surface reflective markers were attached to the participant using two-  
177 sided tape following the procedures outlined by Chu et al<sup>8</sup> (Figure 3) in a validation study of the  
178 marker-based motion capture model of scapular motion. A scapular acromial marker cluster  
179 (AMC) was created using a rigid triangular body and was applied to the posterior acromion  
180 process and medial to the posterior acromion calibration marker (Figure 1B). Recording  
181 scapular motion using and AMC has been found to have excellent within-session reliability  
182 (Intraclass correlation coefficient (ICC): 0.90-0.98) and a standard error of measurement (SEM)  
183 of 2.25° for active arm elevation, protraction, and retraction and has been validated against  
184 gold-standard technique such as dynamic radiography.<sup>8,21</sup> Raw kinematic camera data was  
185 collected at 200Hz and smoothed using a lowpass Butterworth filter with a cut off frequency of  
186 6Hz. Joint coordinate systems and segment parameters for the trunk, pelvis, and scapula were  
187 oriented with the X axis pointed anteriorly, the Y axis oriented superiorly, and the Z axis  
188 oriented laterally (Figure 3).<sup>20</sup> A Euler rotation sequence for scapular motion in the frontal and  
189 transverse planes was resolved as Y-X-Z and calculated relative to the thorax per the ISB  
190 guidelines.<sup>20</sup>

191 *Analysis:*

192 A test-retest design was used to examine the intra-rater reliability of the same examiner  
193 between testing sessions and the inter-rater reliability of two examiners within the same  
194 testing session for clinical measurements recorded with the electric goniometer. Both the intra-  
195 rater and the inter-rater reliability of scapular measurements recorded during rest and  
196 excursion for anatomical plane were assessed with ICC (ICC<sub>2,3</sub>) using the average of three trials

197 of motion. Intraclass correlation coefficients were interpreted as: <0.5 as poor, 0.5-0.75 as  
198 moderate, 0.75-0.90 as good, and >0.90 as excellent reliability.<sup>15</sup> Measurement precision was  
199 determined by calculating the SEM and the minimal detectable change score at the 90%  
200 confidence interval (MDC<sub>90</sub>).<sup>22</sup>

201 The criterion-validity of the electric goniometer to measure total scapular excursion in  
202 each anatomical plane compared to the reference standard of 3D optical motion capture  
203 system was completed using several approaches. First, a paired t-test was used to compare the  
204 average excursion of three trials of motion between the electric goniometer and the 3D optical  
205 motion capture. Alpha was set *a priori*  $\leq 0.05$ , although a Bonferroni correction was applied to  
206 account for the three total comparisons of each condition in each plane. This correction  
207 reduced alpha to  $\leq 0.017$ . Second, the root mean square error (RMSE) was calculated to  
208 determine error associated with electric goniometer compared to the 3D optical motion  
209 capture for each condition. Third, we calculated Bland-Altman plots to observe for the average  
210 difference and limits of agreement (LOA) between the electric goniometer and the 3D optical  
211 motion capture. The LOA was calculated by multiplying the standard deviation of the average  
212 difference by 1.96 to observe the 95% confidence interval.<sup>23</sup> During analysis of the Bland-  
213 Altman plots, a systematic average difference of  $-7^\circ$  was observed for scapular excursions  
214 recorded by the electric goniometer compared to the 3D optical motion capture for scapular  
215 motion measured in the frontal plane. Therefore, a correction of adding  $7^\circ$  to the mean  
216 scapular excursion in the frontal plane was applied to the clinical data.

## 217 **Results:**

### 218 *Reliability:*

219 We observed moderate to good intra-rater reliability for determining scapular rest  
220 position and scapular excursion between testing sessions (Table 1). We observed good to  
221 excellent inter-rater reliability for measuring scapular rest position and moderate to good inter-  
222 rater reliability for measuring scapular excursion within a testing session (Table 2).

223 *Validity:*

224 Validity results are presented in Table 3. The Bland-Altman plots are provided as  
225 supplemental figures. Statistical significance was found between the mean scapular excursions  
226 recorded by electric goniometer and the 3D optical motion capture for in the frontal ( $p < 0.001$ ),  
227 transverse ( $p = 0.015$ ), and the sagittal plane ( $p < 0.001$ ). The RMSE ranged from 7-10°, the  
228 average difference between -7° and 4° (Table 3).

229 **Discussion:**

230 The present study sought to investigate the reliability and validity of the novel electric  
231 goniometer to measure scapular motion in each anatomical plane during arm elevation. The  
232 reliability aim was designed to investigate the intra- and inter-rater reliability of clinical scapular  
233 measurements across days and between examiners. The validity aim was designed to examine  
234 the criterion-validity of measurements recorded by the clinical assessment device compared to  
235 the reference-standard of 3D optical motion capture. The results from this study indicate the  
236 electric goniometer is a reliable device for measuring scapular rest positions and total  
237 excursions in each anatomical plane when a standard operating procedure is used. Further, the  
238 findings from this study indicate the electric goniometer has moderate validity to measure  
239 scapular excursions in all three anatomical planes in a clinical setting.

240 Prior to data collection, we hypothesized that the measurements recorded from the  
241 electric goniometer would not exceed  $10^\circ$  of error compared to the 3D optical motion capture  
242 system. Though the resultant p-values evaluating for significant differences in mean values of  
243 scapular excursions were significant for each anatomical plane, the comparison of means alone  
244 is not sufficient for a complete validity analysis.<sup>24</sup> Therefore, we used a multistep approach  
245 to assess validity using statistics such as RMSE, average difference, and LOA.<sup>23</sup> The threshold of  
246 RMSE was rooted in the notion that  $10^\circ$  of error would exceed both measurement error and  
247 minimal detectable change, such that error over  $10^\circ$  would indicate an invalid measurement of  
248 scapular motion. Additionally, previous literature has indicated that RMSE values above  $10^\circ$  is  
249 indicative of inaccurate measures of true scapular motion.<sup>8,25,26</sup> In the current study, RMSE  
250 values were  $10^\circ$  or less for all planes of motion. Further, the average difference between the  
251 electric goniometer and the 3D motion capture system ranged from  $-7^\circ$  to  $4^\circ$  across the three  
252 anatomical planes. Taken together, these results suggest that the electric goniometer is capable  
253 of measuring scapular motion in each anatomical plane during arm elevation with a moderate  
254 degree of accuracy.

255 The RMSE associated with arm elevation in the frontal plane highlights a limitation with  
256 the use of a 3D optical motion capture using an AMC to capture scapular motion. The AMC  
257 represents the scapula and its motion is recorded by the 14-camera 3D optical motion capture  
258 system to represent scapular movement. A difficulty of the AMC is its placement on the  
259 posterior acromion limiting access to the scapular spine. In Figure's 1B & 1C, the placement of  
260 the electric goniometer is limited to being placed on the medial aspect of the scapular spine  
261 due to the AMC position on the acromion. Thus, the correction applied to frontal plane data,

262 the plane of motion most affected by the AMC, was conducted to reduce the limitations of the  
263 AMC. The correction reduced the RMSE value from  $10^\circ$  to  $7^\circ$  and increased the associated  $p$ -  
264 value to 0.957, indicating no significant difference between the electric goniometer and the 3D  
265 optical system when measuring scapular motion in the frontal plane during arm elevation.

266 There was similar error between the measurement methods during motion in the  
267 sagittal plane. The fact that there was a significant difference between methods, despite an  
268 RMSE of  $9^\circ$  and an average difference of  $4^\circ$ , we suspect that accessory motion from spinal  
269 flexion and extension contributed to the overall differences in scapular measurement. Although  
270 participants were verbally instructed to not move their spine during each trial, and were closely  
271 observed during testing, it was not possible to completely eliminate the inherent motion from  
272 the spine. This concept highlights a limitation of calibrating the electric goniometer to a stand-  
273 alone vertical surface (I-beam square level). To overcome this limitation in the future, we  
274 suggest that the electric goniometer be calibrated to the participant's spine prior to measuring  
275 sagittal plane motions. This adjustment in calibration will ideally capture the inherent trunk  
276 position of the participant and account for any initial spinal offset in the sagittal plane.

277 While each measurement recorded by the electric goniometer introduces a specific  
278 limitation, the comparison between mean excursion values recorded by the device and  
279 previous literature is encouraging. Specifically, the average scapular external rotation observed  
280 in the current study in the transverse plane ( $-8^\circ$ ) is identical to the average scapular external  
281 rotation recorded by the AMC investigated by Chu et al.<sup>8</sup> ( $-8^\circ$ ) and closely similar to the value  
282 observed by McClure et al<sup>3</sup> using bone pins ( $-6^\circ$ ). In addition, the average total excursion value  
283 of scapular posterior tilt recorded by the electric goniometer ( $18^\circ$ ) agreed with the average

284 excursion values using intracortical measurement techniques previously reported by Ludewig et  
285 al<sup>2</sup> (18°). These comparisons to previous literature using gold-standard techniques of  
286 measurement demonstrates promising capabilities of scapular measurement in each  
287 anatomical plane during arm elevation.

288 A strength of this study is the examination of both the between examiner and between  
289 day reliability. Previous studies examining the clinical assessment of scapular motion have been  
290 limited to single examiner within the same day analyses, separated by 30 minutes or less<sup>27,28</sup> or  
291 are absent from reports.<sup>13,29</sup> This study examined the both the intra-rater reliability of the  
292 electric goniometer across two testing sessions and the inter-rater reliability within a single  
293 testing session. The average rest position and the average excursion values from the three trials  
294 of motion were analyzed for reliability. To minimize the risk of error between measurement  
295 techniques, the use of a standardized placement procedures was implemented as described in  
296 the methods section. Our results were consistent with previous investigations of digital  
297 goniometer measurement in finding that there is higher intra-rater reliability than inter-rater  
298 reliability even when a standard procedure is used.<sup>30</sup>

299 In the present study, the electric goniometer was found to be reliable for determining  
300 both scapular rest position (ICC<sub>2,3</sub>: 0.692-0.874) and total excursion (ICC<sub>2,3</sub>: 0.628-0.790) across  
301 an average of 9 days. There was less associated error when measuring rest position (SEM: 2-3°)  
302 than during the measurement of scapular excursions (SEM: 2-4°). The decrease in ICC values  
303 and increase in SEM between rest and excursion measurement could be linked to variations in  
304 movement patterns of individuals across days. Further, the inter-rater reliability on the same  
305 day of testing to determine scapular rest position (ICC<sub>2,3</sub>: 0.833-0.912) across all three

306 anatomical planes was higher than those reported by Watson et al. (ICC: 0.21-0.52).<sup>28</sup> Reliability  
307 for total scapular excursion (ICC<sub>2,3</sub>: 0.545-0.724) in the present study was also higher than  
308 reported by Watson et al. (ICC: 0.23) during arm elevation.<sup>28</sup> These results demonstrating  
309 increased of inter-rater reliability facilitate the concept that the electric goniometer is reliable  
310 when used by multiple raters within a single testing session.

311 This study is not without limitations. First, the electric goniometer serves as a surface-  
312 based assessment approach which is affected by soft tissue obstruction and movement. As  
313 reported in the literature, scapular clinical assessment is limited by the presence of soft tissue  
314 and skin movement artifact.<sup>18,21,31</sup> This limitation was apparent during the measurement of  
315 scapular motion in the frontal plane during the condition of arm elevation, where a correction  
316 was necessary to account for an average difference of -7°. Additionally, attempting to measure  
317 the scapula during sagittal plane motion may be inhibited by soft tissues bunching posteriorly  
318 during active movement. Conversely, scapular motion in the sagittal plane introduces the  
319 difficulty in palpating the scapula as it wraps around the thorax, making the prominent bony  
320 aspects on the scapula difficult to discern. As a result of this difficulty, the authors feel that  
321 either teaching videos or hands-on training with the device prior to implementation to practice  
322 or research may be necessary. Another limitation in the present study was the sample  
323 population. Participants in the current study were asymptomatic and did not have any current  
324 shoulder pathology. This highlights a constraint to the clinical application of the electric  
325 goniometer as a screening tool versus a diagnostic device based on this study. Future research  
326 should include patients with pathological shoulders to determine if scapular motion measured  
327 with the electric goniometer can discriminant between healthy and pathological states.

328           Ultimately, the results from this investigation demonstrate that the IMU equipped  
329 electric goniometer is a reliable and moderately valid device to measure scapular motion in  
330 each anatomical plane during arm elevation in a healthy population. The degree of error  
331 associated with the device when measuring scapular motion excursions is dependent on the  
332 presence of soft-tissue and palpation restrictions. The authors recommend that a clear and  
333 defined standard operating procedure be used when scapular measurements are taken  
334 between examiners. This information provides evidence of a clinically portable and consistent  
335 device to objectively measure scapular motion in the clinical setting.
