Abstract

Alterations in the lumbo-pelvic coordination denote changes in neuromuscular control of trunk motion as well as load sharing between passive and active tissues in the lower back. Differences in timing and magnitude aspects of lumbo-pelvic coordination between patients with chronic low back pain (LBP) and asymptomatic individuals have been reported; yet, the literature on lumbo-pelvic coordination in patients with acute LBP is scant. A case-control study was conducted to explore the differences in timing and magnitude aspects of lumbo-pelvic coordination between females with (n=19) and without (n=19) acute LBP. Participants in each group completed one experimental session wherein they performed trunk forward bending and backward return at preferred and fast paces. The amount of lumbar contribution to trunk motion (as the magnitude aspect) as well as the mean absolute relative phase (MARF) and deviation phase (DP) between thoracic and pelvic rotations (as the timing aspect) of lumbo-pelvic coordination were calculated. The lumbar contribution to trunk motion in the 2nd and the 3rd quarters of both forward bending and backward return phases was significantly smaller in the patient than the control group. The MARF and the DP were smaller in the patient vs. the control group during entire motion. The reduced lumbar contribution to trunk motion as well as the more in-phase and less variable lumbo-pelvic coordination in patients with acute LBP compared to the asymptomatic controls is likely the result of a neuromuscular adaptation to reduce painful deformation and to protect injured lower back tissues.

Acute low back pain; Trunk forward bending and backward return; Lumbo-pelvic coordination; Timing and magnitude aspects; Continuous relative phase

INTRODUCTION

Lumbo-pelvic coordination during trunk forward bending and backward return is often assessed by clinicians to better identify biomechanical abnormalities in patients with low back pain (LBP) (Esola et al., 1996; Hestøek and Leboeuf-Yde, 2000; Whittaker, 2007). Alterations in lumbo-pelvic coordination denote changes in neuromuscular control of trunk motion as well as changes in the load sharing between passive and active components of the lower back (Davis and Jorgensen, 2005; Davis et al., 1965; Farfan, 1975; Hashemirad et al., 2010). Both neuromuscular control and load sharing have been recognized to play a role in LBP development (Abouhossein et al., 2011; Dubois et al., 2011; Hashemirad et al., 2009; Leinonen, 2003; Panjabi, 2003; van Dieën and Nussbaum, 2000). The assessment of lumbo-pelvic coordination may simply involve evaluation of the relative contributions of lumbar flexion and pelvic rotation to trunk motion at the end range of forward bending or may include more in-depth evaluation of timing and magnitude of such relative contributions throughout the course of motion (Kim et al., 2013; Lariviere et al., 2000; Mokhtarinia et al., 2016; Pries et al., 2015; Silfies et al., 2009).

In asymptomatic individuals, the lumbar contribution to forward bending has been reported to be dominant in the early stage of trunk motion, whereas pelvis contribution increases toward the end of motion and is dominant at the late stage of motion (Esola et al., 1996; Lee and Wong, 2002; Pal et al., 2007; Tafazzol et al., 2014; Vazirian et al., 2016a; Vazirian et al., 2017; Vazirian et al., 2016b). Conversely, backward return starts with a small lumbar contribution that gradually increases toward the end of motion (Granata and Sanford, 2000; Lee and Wong, 2002; McClure et al., 1997; Pal et al., 2007). In terms of timing of motion, it has been reported that in forward bending, lumbar motion tends to start sooner than pelvic motion and lumbar motion remains ahead of pelvic motion throughout the forward bending. In the backward return lumbar motion remains behind pelvic motion (Pal et al., 2007; Thomas and Gibson, 2007). Compared to asymptomatic individuals, lumbo-pelvic coordination in patients with LBP is generally more in-phase and less variable and involves smaller lumbar contribution to the trunk motion (Mokhtarinia et al., 2016; Seay et al., 2011; Selles et al., 2001). There are, however, some exceptions to such general trend of observed differences in the literature which could be due to heterogeneity of LBP (e.g., different subtypes of LBP), differences in patient's personal characteristics, and difference in performing forward bending and backward return (e.g., pace of task, presence of load, etc.) (Granata and Sanford, 2000; Kim et al., 2013; Silfies et al., 2009; Van Wingerden et al., 2008; Vazirian et al., 2016b). Kim et al. (2013), for instance, observed larger lumbar contribution to the trunk motion in a subgroup of patient with LBP who were identified to have "lumbar flexion with rotation syndrome". Silfies et al. (2009) reported a less in-phase and more variable lumbo-pelvic coordination in patients with LBP compared to asymptomatic controls under a reaching task. Despite considerable research related to

lumbo-pelvic coordination, most of prior studies included patients with chronic LBP and it is not clear whether their findings can be generalized to include also patients with acute LBP. Due to the simplicity of the assessment, an evaluation of lumbo-pelvic coordination in clinical practice could prove useful to identify biomechanical etiologies for LBP and to direct patient treatment; thus a further understanding of this construct in acute LBP is needed.

Authors of the present study have recently reported the differences in lumbo-pelvic coordination between patients with acute LBP and asymptomatic controls by calculation of the relative contributions of lumbar and pelvis to trunk motion at the end point of forward bending. Compared to asymptomatic controls, patients with LBP implemented smaller lumbar flexion and larger pelvic rotation when bending from standing posture to the end point of forward bending. These results clearly distinguished patients from asymptomatic controls in discrete end points, however, they don't offer any information related to potential differences in lumbo-pelvic coordination throughout the trunk forward bending and backward motion. Further characterization of lumbo-pelvic coordination throughout the entire task cycle could provide more in-depth information about the impact of acute LBP on timing and magnitude aspects of lumbo-pelvic coordination (Mokhtarinia et al., 2016; Pal et al., 2007; Selles et al., 2001; Thomas and Gibson, 2007; Vazirian et al., 2016b). In other words, potential biomechanical abnormalities in the lower back of patients with LBP, particularly due to neuromuscular impairments, could be better identified by assessment of lumbo-pelvic coordination throughout the entire task. Therefore, the objective of this study was to investigate differences in timing and magnitude aspects of lumbo-pelvic coordination between patients with acute LBP and asymptomatic controls during forward bending and backward return. Lumbar contribution to the trunk rotation was investigated at each quartile of forward bending and backward return as the magnitude aspect of lumbo-pelvic coordination. The timing aspect of lumbo-pelvic coordination was investigated using the continuous relative phase method (Lamb and Stöckl, 2014). We hypothesized that patients with acute LBP would display a more in-phase and less variable lumbo-pelvic coordination that involves a reduced lumbar contribution to the trunk motion compared to the asymptomatic controls during the entire period of the forward bending and backward return task.

METHODS

Study Design and Participants

A case-control study design was used wherein 19 female patients (aged 40–70 years old) with acute LBP (health care provider-diagnosed LBP $\geq$ 3 months) completed a set of trunk forward bending and backward return tasks. Data for 19 asymptomatic female controls (aged 40–70 years old) were extracted from an earlier study (Vazirian et al., 2016a). All participants completed an informed consent procedure approved by the University of Kentucky Institutional Review Board before participation. Age, stature, body mass, and body mass index (BMI) for the two groups were comparable (Table.1). Asymptomatic controls with any history of LBP or musculoskeletal disorders were excluded (Shojaei et al.,

2016; Vazirian et al., 2016a). Patients with acute LBP were excluded if they had any significant cognitive impairment, intention to harm themselves or others, or substance abuse.

Experimental Procedures

Two wireless Inertial Measurement Units (IMUs; Xsens Technologies, Enschede, Netherlands) were attached superficial to the T10 and the S1 spinous process of participants to collect kinematics of thorax and pelvis as rigid bodies (50 Hz). A Kalman filter was used to minimize any potential effect of noise on the data. Each participant completed two trunk forward bending and backward return tasks in the sagittal plane; one at a preferred pace and the other at a fast pace. During the task with preferred pace, participants stood in an upright posture for 5 seconds, bent forward using a preferred pace to reach their maximum trunk rotation, held their maximum trunk rotation for 5 seconds, returned back to the initial upright position, and stood again for 5 seconds. During the task with fast pace, participants performed the same task but with their fastest possible pace and without a pause at the maximum trunk rotation. Each task pace was repeated three times, and participants completed the task with the preferred pace prior to the task with the fast pace.

Data analysis

Using the kinematics data collected with the IMUs, pelvic and thoracic rotations were found with respect to the standing posture. At each time instant, flexion/extension of lumbar spine (i.e., as a deformable segment between thorax and pelvis) was calculated as the difference between the pelvic and thoracic rotations. To calculate the lumbar contribution, the forward bending and the backward return of each task was divided into quarters of equal thoracic rotation. The ratio of range of lumbar flexion/extension over the range of thoracic rotation was then calculated for each quartile. Lumbar contribution in each quartile of forward bending and backward return task was finally calculated as the average of the above ratio for the same quartile across the three repetitions of the task. The thoracic and pelvic rotation data were also used to calculate the continuous relative phase between thorax and pelvis by initially generating the phase planes of pelvic and thoracic rotations according to (Lamb and Stöckl, 2014), and then subtracting the pelvic phase angle from the thoracic phase angle at each instant of the task. To characterize the timing aspect of lumbo-pelvic coordination, two measures from the continuous relative phase (CRP) curve of forward bending and backward return were extracted: 1) the mean absolute relative phase (MARP), and 2) the deviation phase (DP) (Stergiou et al., 2001). Briefly, the mean and standard deviation of the absolute value of relative phase for each percentile of trunk forward bending and backward return across the three repetitions of each task were initially obtained. Subsequently, the average of the calculated mean and standard deviation values over the entire forward bending and backward return were respectively calculated as MARP and DP values. By definition, MARP values closer to 0 represent a more “in-phase” lumbo-pelvic coordination (i.e., more synchronous movement of segments) whereas values closer to π radians represent a more “out-of-phase” lumbo-pelvic coordination (i.e., less synchronous movement of segments). Moreover, a smaller DP represents a lumbo-pelvic coordination with less trial-to-trial variability (i.e., a more stable motion pattern).

Statistical Analysis

For each task and phase of trunk motion (i.e., forward bending and backward return), the lumbar contribution in each quartile, MARP, and DP were extracted for statistical analyses. All statistical procedures were conducted in SPSS (IBM SPSS Statistics 23, Armonk, NY, USA), and in all cases a p value smaller than 0.05 was considered as statistically significant. Mixed-model analysis of variance (ANOVA) tests were conducted on the dependent variables with group (with and without LBP) and age (40–50, 50–60, 60–70) as the between-subjects factors and motion pace (preferred and fast) as the within-subjects factor. Mixed-model ANOVA assumptions were verified, and significant ANOVA tests were followed by post hoc tests using Tukey's procedure.

RESULTS

Interaction effects

Forward bending—The lumbar contribution in the 1st quarter was larger (40–50: $F=4.95$, $p=0.045$; 60–70: $F=7.90$, $p=0.016$) in the control vs. patient group only during the task with fast pace and for individuals in the 40–50 (40s) and 60–70 (60s) year-old age groups (Fig. 1). This lumbar contribution was also larger ($F=10.47$, $p=0.018$) in the task with preferred vs. fast pace only for patients in the 60–70 (60s) year-old age group (Fig. 1).

Additionally, lumbar contribution in the 4th quarter was larger ($F=6.22$, $p=0.041$) in the task with preferred vs. fast pace only for patients in the 50–60 (50s) year-old age group. This lumbar contribution was also larger ($F=5.97$, $p=0.012$) in the 60–70 (60s) versus 50–60 (50s) year-old age group only among patients and under task with fast pace (Fig. 2).

Backward return—The lumbar contribution in the 1st quarter was larger ($F=14.71$, $p=0.012$; $F=9.37$, $p=0.022$) during the task with preferred vs. fast pace only for controls in the 40–50 (40s) and 60–70 (60s) year-old age group (Fig. 3). This lumbar contribution was also larger ($F=5.01$, $p=0.020$) for controls in the 40–50 (40s) vs. controls in the 50–60 (50s) year-old age group (Fig. 3).

Additionally, the lumbar contribution in the 4th quarter was larger ($F=5.12$, $p=0.043$) for controls in the 60–70 (60s) year-old age group vs. patients in the same age group only during the task with fast pace (Fig. 4). This lumbar contribution was also larger ($F=17.62$, $p=0.009$) in the task with preferred vs. fast pace only for controls in the 50–60 (50s) year-old age group (Fig. 4). Furthermore, this lumbar contribution was larger ($F=21.26$, $p=0.004$) during the task with preferred vs. fast pace only for patients in the 60–70 (60s) year-old age group (Fig. 4).

Group differences—During forward bending and backward return, the lumbar contribution in the 2nd and 3rd quarters was smaller in the patient group than the control group (Table 2 and Table 3). Furthermore, the MARP and DP were smaller in the patient vs. control group during forward bending and backward return (Table 2 and Table 3).

The effects of task pace—Lumbar contribution to the trunk rotation was smaller during the 2nd and 3rd quarters of both forward bending and backward return of the task with fast

vs. preferred pace (Table 3). MARP during forward bending and DP during both forward bending and backward return were smaller in the task with fast vs. preferred pace (Table 2 and Table 3).

Age-related differences—Lumbar contribution to the trunk rotation during the 2nd and 3rd quarters of both forward bending and backward return was larger in the 40–50 (40s) year-old age group than the other two age groups (Table 3). No age related differences in MARP and DP during forward bending and backward return were found (Table 2 and Table 3).

DISCUSSION

The purpose of this study was to investigate differences in magnitude and timing aspects of lumbo-pelvic coordination between patients with acute LBP and asymptomatic controls during trunk forward bending and backward return. Lumbar contribution to the trunk motion in the 2nd and 3rd quarters of forward bending and backward return were smaller in patients with acute LBP vs. asymptomatic controls (i.e., partially confirming our hypothesis). Lumbo-pelvic coordination was more in-phase (i.e., denoted by smaller MARP values) and less variable (i.e., denoted by smaller DP values) in patients with acute LBP vs. asymptomatic controls (i.e., confirming our hypothesis).

In our earlier study, lumbar contribution to the trunk motion at the end point of the forward bending was observed to be smaller in patients with acute LBP vs. asymptomatic controls. Our current finding, further suggest that such overall observed difference was due to smaller lumbar contribution in patients with acute LBP in the 2nd and 3rd quarters of forward bending and backward return. To the best of our knowledge, no other study has reported differences in lumbar contribution to trunk motion throughout the forward bending and backward return between patients with acute LBP and asymptomatic controls. However, in studies including patients with chronic LBP and individuals with a history of LBP similarly smaller lumbar contribution to the trunk motion in all quartiles (Lariviere et al., 2000) as well as in the early stage (Porter and Wilkinson, 1997) or middle stage (Esola et al., 1996) of forward bending and backward return have been reported.

While in the current study the patients implemented a more in-phase motion of pelvis and thorax segments compared to asymptomatic controls, Wong and Lee (2004) reported no differences in timing aspects of the lumbo-pelvic coordination between a patient group and a asymptomatic control group. Such inconsistency in the results between the current study and the study by Wong and Lee (2004) could be due to the differences in the personal characteristics of participants (e.g., females ~ 57 years old in the current study vs. males ~ 40 years old in the study by Wong and Lee (2004)), different methods of data analysis (CRP method in the current study vs. Cross-correlation method in the study by Wong and Lee (2004); see Vazirian et al. (2016b) for differences between the two methods) and potential differences in LBP subtypes. In studies including patients with chronic LBP, there are reports of a more in-phase lumbo-pelvic coordination in patients vs. asymptomatic controls during forward bending and backward return (Asgari et al., 2015; Mokhtarinia et al., 2016) as well as during walking and running (Seay et al., 2011; Selles et al., 2001). In contrast,

Silfies et al. (2009) and Paquet et al. (1994) reported, respectively, a more out-of-phase and similar lumbo-pelvic coordination in patients vs. asymptomatic controls. Discrepancies in the results of studies concerning patients with chronic LBP may be attributed to the differences in the population studied (e.g., personal characteristics and LBP subtype), differences in the methods of data analysis, and differences in LBP severity at the time of study.

The smaller contribution of lumbar flexion to trunk motion, as seen in patients with acute LBP in the current study, reduces passive contribution of lower back tissues in offsetting the physical demand of the task on the lower back. Such an alteration in lumbar contribution has been suggested to prevent painful deformation in posterior elements of the ligamentous spine (Colloca and Hinrichs, 2005). More in-phase and less variable lumbo-pelvic coordination, also known as phase-locked or rigid coordination (Mokhtarinia et al., 2016), is regarded as a protective motor control strategy to reduce the likelihood of painful deformation of spinal tissues under dynamic tasks. Such a strategy, however, demands higher levels of trunk muscles activation and co-activation which in turn can lead to increased spinal loads and muscle fatigue (Bazrgari et al., 2008a, b; Marras et al., 2001).

The lumbar contribution in the 2nd and 3rd quarters was smaller during the task with fast vs. preferred pace for both forward bending and backward return. Similarly, MARP and DP were found to be smaller during the task with fast pace. These findings are consistent with earlier reports on the effects of task pace on trunk kinematics variability (Asgari et al., 2015). The smaller lumbar contribution and more in-phase lumbo-pelvic coordination is consistent with the strategy to prevent painful deformation and injury (intensified by viscoelastic behavior and inertial demand of fast tasks) given the higher risk of injury under fast trunk motion (Bazrgari et al., 2008c).

Better understanding of differences in lumbo-pelvic coordination during trunk forward bending and backward return between individuals with and without LBP is clinically important (Panjabi, 2003; Van Hoof et al., 2012; White III and Panjabi, 1978). Specifically, quantification of such differences, as done in the present study, may improve the effectiveness of current management paradigm for LBP by positively impacting the diagnosis and treatment stages. More in-depth information about normal and abnormal trunk kinematics during trunk forward bending and backward return can help better match patient pathology with targeted treatments and decide whether a given treatment is moving the patient in the right direction. Additionally, our results indicate that lumbo-pelvic coordination varies with age which also should be considered in the diagnostic process.

Although our findings contribute to the current understanding of the timing and magnitude of lumbar spine contribution to the trunk forward bending and backward return in patients with acute LBP, there are study limitations. First due the use of cross sectional data, we are unable to infer causality. As such we are unable to infer if study findings result in or are consequence to acute LBP. Second, we did not control for intersubject variability such as anthropometric measures, pain level, potential musculoskeletal abnormalities like foot shape abnormalities, flat back, hyper-lordosis as well as LBP-related disability, fear of movement, and general health status. With this being said, there is the possibility of additional unknown

factors that affect study outcomes and were not included in our analysis. Third, although we controlled for age and gender-related differences, the influence of differences in lumbar spine stiffness or mobility between groups on our finding, though perhaps minimal, should not be overlooked. Finally, while studying magnitude and timing aspects of lumbo-pelvic coordination in patients with acute LBP provides some insights into neuromuscular control of trunk motion and load sharing between lower back tissues, quantification of such variables requires detailed model-based studies (Arjmand et al., 2009; Bazrgari et al., 2008a) which we plan to conduct in the future.

In summary, the lumbar contribution to trunk motion during the 2nd and 3rd quarters of trunk forward bending and backward return phases of motion as well as MARP and the DP during the entire motion were smaller in the patient vs. the control group. These differences in lumbo-pelvic coordination of individuals with acute versus without acute LBP are likely to be due to a neuromuscular motor control strategy to temporarily reduce the painful deformations in the lumbar tissues.

Figure 1.

The simple main effects of group (a) and task pace (b) on lumbar contribution (LC) were significant in the 1st quarter of forward bending. Error bars indicate positive standard deviations. The symbols * and + indicate significant paired differences.

Figure 2.

The simple main effects of task pace (a) and age (b) on lumbar contribution (LC) were significant in the 4th quarter of forward bending. Error bars indicate positive standard deviations. The symbol * indicates significant paired differences.

Figure 3.

The simple main effects of task pace (a) and age (b) on lumbar contribution (LC) were significant in the 1st quarter of backward return. Error bars indicate positive standard deviations. The symbols * and + indicate significant paired differences.

Figure 4.

The simple main effects of group (a) and task pace (b and c) on lumbar contribution (LC) were significant in the 4th quarter of backward return. Error bars indicate positive standard deviations. The symbol * indicates significant paired differences.

Table 1

Mean (SD) participants characteristics

Group	Controls	Patients	<i>t</i> -value	p-values
Age (years)	56 (9)	58 (9)	0.723	0.474
Stature (m)	1.64 (5)	1.63 (7)	−0.592	0.557
Body mass (kg)	70(12)	76(17)	1.553	0.130
BMI	25.7(4.1)	27.5(4.6)	1.608	0.117

Table 2

Summary of statistical results for all outcome measures during trunk forward bending and backward return. LC: lumbar contribution. MARP: mean absolute relative phase. DP: deviation phase.
