Abstract

Cells within salamander limbs retain memories that inform the correct replacement of amputated tissues at different positions along the length of the arm, with proximal and distal amputations completing regeneration at similar times. We investigated the possibility that positional memory is associated with variation in transcript abundances along the proximal-distal limb axis. Transcripts were deeply sampled from *Ambystoma mexicanum* limbs at the time they were administered fore arm vs upper arm amputations, and at 20 post-amputation time points. After amputation and prior to regenerative outgrowth, genes typically expressed by differentiated muscle cells declined more rapidly in upper arms while cell cycle transcripts were expressed more highly. These and other expression patterns suggest upper arms undergo more robust tissue remodeling and cell proliferation responses after amputation, and thus provide an explanation for why the overall time to complete regeneration is similar for proximal and distal amputations. Additionally, we identified candidate positional memory genes that were expressed differently between fore and upper arms that encode a surprising number of epithelial proteins and a variety of cell surface, cell adhesion, and extracellular matrix molecules. Also, genes were discovered that exhibited different, bivariate patterns of gene expression between fore and upper arms, implicating dynamic transcriptional regulation for the first time in limb regeneration. Finally, 43 genes expressed differently between fore and upper arm samples showed similar transcriptional patterns during retinoic acid-induced reprogramming of fore arm blastema cells into upper arm cells. Our study provides new insights about the basis of positional information in regenerating axolotl limbs.

Keywords

Axolotl; limb regeneration; transcription; positional memory

1. Introduction

Salamander limb regeneration provides an excellent model to identify endogenous mechanisms of tissue repair that might one day be translated to humans. A fundamental question in the limb regeneration field concerns the basis of positional information in cells along the proximal-distal axis (McCusker and Gardiner, 2014; Bryant and Gardiner, 2016). How do limb cells that survive an amputation injury orchestrate a reparative response that reforms the appropriate distal structures? Seemingly, progenitor cells have position-specific information prior to amputation or gain this information during regeneration. The basis of this information may be a quantitative property of cells or components of the nearby extracellular environments that cells create and maintain. For example, retinoic acid treatment of a distal limb stump reprograms blastema cells to a proximal positional identity (Maden, 1982), likely by altering gene expression (Nguyen et al., 2017). Also, when distal blastema cells are grafted into proximal blastema sites, their cellular movements suggest positional information is communicated via cell surface proteins (da Silva et al., 2002; Echeverri and Tanaka, 2005; Kumar et al., 2007). Additionally, positional information may correlate with other cell properties including cell adhesion, composition of extracellular environments, and bioelectricity, which likely regulate cell fate decisions during proximal-distal limb regeneration (Levin, 2014; McCusker et al., 2015; Phan et al., 2015).

Somewhat associated with the question of positional memory concerns the rate at which regeneration proceeds along the proximal-distal axis. The time from amputation to the completion of regeneration is similar regardless of where an amputation is performed along the limb axis (Iten and Bryant, 1973; Stocum, 1980). Surprisingly, limbs that are amputated at different anatomical positions pass through stages of regeneration at the same time, but more overall growth occurs in proximal amputations to replace the greater amount of missing tissue. In other words, it takes a similar amount of time for a salamander to regenerate an elbow, fore arm, and hand after an upper arm amputation as it does to regenerate a hand after an amputation through the wrist. Why the time to complete regeneration evolved to be similar along the limb axis is curious enough, but equally curious is the nature of the mechanisms that alter regeneration to achieve a similar offset timing.

Here we investigate the possibility that positional memory and regeneration timing are properties of transcriptional control. We reasoned that cells sampled from different anatomical positions at the time of amputation and during regeneration would express different transcripts associated with positional information and regeneration timing. Further, we reasoned that by filtering these genes against an existing list of genes that showed differential expression in response to retinoic-acid treatment (Nguyen et al., 2017), we would identify candidates for positional information. Within these contexts, we report differentially expressed genes, highlighting candidates that are most likely to provide new insight about the basis of positional information and regeneration timing in axolotl limbs.

2. Materials and methods

2.1 Gene expression analysis

The experimental design and methods for collecting tissues, isolating RNA, and performing microarray analysis were previously detailed in Voss et al. 2015 (Figure 1). That study generated comprehensive gene expression datasets for axolotl fore and upper arm regeneration, but only presented results of the fore arm regeneration dataset. Here, we use both datasets to identify genes that were expressed differently between fore and upper arm tissue samples at the time of amputation (Day 0: D0) and during specific intervals of time during the first 28 days of limb regeneration: D0–0.1, D1–D2, D3–D9, D10–D16, D16–D20, D20–24, and D24–D28. Day 0 consisted of a 1 mm thick heterogeneous cross section of limb across the amputation plane. Post-amputation, tissue was collected within 1 mm of the distal blastema tip. For each time interval, the average expression difference was calculated on a gene-by-gene basis between fore and upper arm replicate samples. All genes that exhibited a $> 1.0 \log_2$ average expression difference were retained for gene enrichment analysis using Panther Gene Expression tools (Mi et al., 2013), or manual curation using literature mined from Gene and PubMed databases at the National Center for Biotechnology Information (NCBI). GO terms were reported if they met a Bonferroni corrected p-value < 0.05 , as implemented in the Panther statistical overrepresentation test. The fore and upper arm data are available in the Gene Expression Omnibus at NCBI.

2.2 Immunohistochemistry

Experimental procedures involving axolotls were approved by IACUC of Northeastern University under protocol number 15-1244R. Amputated limbs were collected from animals 6 cm in total length (RRID:AGSC_100J) and fixed overnight in 4% paraformaldehyde at 4 °C. Limbs were then cryoprotected in 30% sucrose and cryosectioned at 30 μm from each the center of the proximal limb segment and distal limb segment. Limb sections were stained for myosin heavy chain (DSHB MF-20) overnight at 4 °C and muscle and bone were quantified as a fraction of the total area of the tissue section. Area was quantified using FIJI/ImageJ (Schindelin et al 2012) to determine the relative fraction of pixels contained within each region.

3. Results and Discussion

3.1 Identification of differently expressed genes

Previously, we reported on a highly-powered, transcriptional study of axolotl fore arm regeneration. In that study, tissue was collected at the time of amputation and at 19 post-amputation time points during the first 28 days of regeneration, using 10 biological replicates for each time point. To complement this body of work, we report on an equally powered dataset based on an upper arm amputation. We used fore and upper arm data to identify genes expressed differently at the time of amputation and during regeneration, as these genes might provide perspective on the molecular basis of positional information. A comprehensive description of the upper arm data will be presented elsewhere; here, we focused attention on transcriptionally and biologically significant time intervals that were discovered in the previous study of axolotl fore arm amputation. The time intervals were: 0–

0.5 DPA (initial burst of transcription), 1–2 DPA (phase of decreasing transcription), 3–9 DPA (pre-bud stage), 10–16 DPA (early bud stage), 16–20 DPA (medium bud stage), 20–24 DPA (late bud stage), and 24–28 DPA (pallet stage). Quality control analyses found the 12–16 DPA upper arm samples to be outliers as all gene expression estimates for microarray probe sets were reduced in magnitude relative to all other samples (Supplemental File 1). These samples and the corresponding fore arm samples were removed and thus the 10 DPA and 18–20 DPA interval were investigated to identify differently expressed genes. Preliminarily, we investigated the utility of several distance metrics (Kullback-Liebler divergence, Euclidean distance L1, and the Bhattacharyya distance) to identify genes with divergent expression estimates between the fore and upper arm datasets, before deciding to focus on genes with $> 1.0 \log_2$ average expression difference in transcript abundance. This conservative approach identified genes with large expression differences between the fore and upper arm datasets, and included high variance genes with large standard deviations of mean expression. In several cases, high variance genes showed bivariate and not continuous expression, implicating dynamic temporal expression for the first time in limb regeneration. Overall, 584 genes (Supplemental File 2) were identified and these significantly enriched Protein Class, Biological Process, Cellular Component, Molecular Function, and Reactome Network Gene Ontology terms (Table 1). Below we present and discuss genes and GO terms in the temporal order of their discovery.

3.2 Comparison of Bone and Muscle Anatomy in Fore and Upper Arms

Progenitor cells in the axolotl limb are poised to regenerate appropriate distal tissues, regardless of where an amputation is performed. This suggests that limb cells contain positional information prior to injury, however it is difficult to know if differences discovered along the proximal-distal limb axis are anatomical or positional in nature. For example, fore and upper arms both contain skeletal muscle and bone, but the muscles and bones are different between these limb segments and therefore may contribute different cell proportions when sampled for gene expression analysis (Pantalacci et al., 2017). To gain insight about anatomical differences, we sectioned fore and upper arms and used immunological staining to quantify the relative proportion of muscle and bone tissue. The relative cross-sectional area of bone but not muscle differed significantly between fore and upper limbs (Fig. 2). Thus, proximal-distal expression differences were somewhat expected for bone and cartilage-associated genes, but not muscle.

3.3 Genes expressed differently at the time of amputation

Most of the genes that were expressed differently at the time of amputation (Supplemental File 2) are typically expressed in differentiated muscle cells, including a diversity of myosins and myosin-associated proteins that enriched muscle contraction, muscle organ development, and cytoskeletal GO terms (e.g. *calponin 1*, *crystallin alpha B*, *g protein-coupled receptor 37-like 1*, *heat shock protein b1*, *myosin binding protein C1–3*, *myosin binding protein H*, *myosin heavy chains 1–4*, *6*, *7b*, & *8*, *myosin light chains 1–4*, *myosin light chain*, *phosphorylatable*, *myosin 18b*, *myomesin 1 & 2*, *small muscle protein x-linked*, *tropomodulin 1*, *tropomyosins 1, 2, c1, t1, & t3*, *tropomyosins 1, 2, & 3*, *triadin*, *titin*). Transcripts for these muscle-associated genes were more abundant in fore arm at the time of amputation (Fig. 3). This suggests that basal transcriptional activity is higher in fore arm muscle because

the proportion of muscle tissue did not differ significantly between upper and lower limbs. After D0, muscle-associated genes decreased in both fore and upper arms through D16, but the initial decrease (D0–D0.5) was steeper in upper arm samples. This pattern of declining transcript abundance was described earlier (Monaghan et al., 2009; Voss et al., 2015). The Voss et al study (2015) noted that the pattern was highly correlated across muscle-associated genes within tissue replicates, suggesting a mechanism that coordinately regulates transcription within muscle cells as they undergo reprogramming or cell death, and/or histolysis at the tissue level. Consistent with the idea of cell death, *caspase 7* (*casp7*) was expressed more highly in upper arm samples before and after amputation, suggesting differential muscle cell death in proximal versus distal amputations within the first day post-amputation. However, the differential expression of *SET and MYND domain containing 1* (*smyd1*), a regulator of end stage muscle differentiation and myogenesis, persisted until day 9, suggesting proximal-distal differences in muscle satellite cell pools during the first 9 days of regeneration. These expression patterns may explain why muscle-associated genes showed a steeper decline after amputation in upper arm samples, as rapid changes to muscular composition after cell death and satellite cell pools would yield the patterns observed. Moreover, more rapid histolysis of muscle tissue and other components of the injury environment in upper arm amputations may explain why the overall time to complete regeneration is similar, regardless of where an amputation is performed (Iten and Bryant, 1973; Stocum, 1980).

If positional information is present in cells prior to amputation, this might be reflected in the differential expression of transcription factors that regulate cell identity. The enrichment analysis suggested that our overall list of 584 genes included significantly fewer DNA-binding proteins than would be expected by chance sampling given the number represented on the microarray (Bonferoni corrected probability = $9.88\text{E-}03$). However, we note that *fos proto-oncogene* (*fos*) and *cysteine rich angiogenic inducer 61* (*cyr61*) showed higher initial expression in fore arms at the time of amputation, and the expression profiles of these genes during regeneration were mirrored by other early immediate genes (Fig. 4). Voss et al 2015 highlighted the immediate early genes as an example of dynamic, highly coordinated gene expression across the entirety of limb regeneration. While these genes mostly showed the same dynamic pattern of expression in fore and upper arms, it is possible that small (< 2 fold expression difference) but consistent differences in transcription factor abundances (e.g. *meis homeobox 2 – meis2*, *homeobox A13 – hoxa13*) may instruct different proximal-distal positional identities during regeneration (Fig. 4). *meis2* and *hoxa13* are known to specify proximal and distal progenitor cell identities, respectively, during limb development and regeneration.

Positional information may also be conferred by proteins that mediate cell-cell and cell-extracellular matrix adhesion, or genes whose products constitute, organize, and regulate properties of the extracellular environment. Genes that fit these categories were expressed differently between fore and upper arms at the time of amputation (Fig. 5). Genes expressed more highly in upper arm encode proteins that regulate cytoskeletal organization (*ras homolog family member a*) and extracellular signaling (*galectin 1*, *galectin 3*, *galectin 8*, *mucin 19*, *brevican*, *periostin*, *chordin-like 1*). We note that *chordin-like 1* (*chrdl1*) was also identified by Bryant et al. (2017) as proximally enriched during axolotl limb regeneration. A

greater number of genes were expressed more highly in fore arm samples, and several of these encode proteins associated with cartilage (*collagen 9a1*, *collagen 9a2*, *collagen 9a3*, *cap-gly domain containing linker protein 1*, *epiphykan*, *lectin 1*, *matrilin 1*); this may reflect the greater relative contribution of bone and cartilage tissue to fore arm samples. Cell adhesion (*thrombospondin 4*, *c-type lectin 3a*) and extracellular matrix (ECM) (*mucin 2*, *uromodulin*, *placenta expressed transcript 1*, *otospiralin*, *tectorin alpha*, *matrilin 4*) genes were also expressed more highly in fore arm samples. We noticed that several of the ECM genes encode Van Willebrand and zona pellucida domains typical of gel and filament forming glycoproteins. These include three presumptive *uromodulin* (*umod*) paralogs that were all expressed more highly in fore arm, *fc fragment of IgG binding protein* which was expressed more highly in upper arm, and two presumptive *tectorin alpha* parlogs, one expressed more highly in fore arm and the other in upper arm. Moreover, these genes were also expressed differently during regeneration. While gel and filament forming glycoproteins are generally thought to coat epithelial surfaces as a defense against pathogens, their differential expression along the proximal distal axis may affect how epithelial cells signal to underlying mesenchymal cells during regeneration. Also, as components of the wound environment, they may provide persistent and reliable cues to progenitor cells during regeneration. We note that *umod* and *thyroid hormone down-regulated protein 20* (*thdl20*) (Fig. 5) were expressed differently across the entirety of limb regeneration (excepting 10 DPA) and are known to be expressed in amphibian epithelia (Furlow et al., 1997; Page et al., 2009).

In concluding this section, we report a novel finding that was revealed by our deep sampling of fore and upper arm tissues. Bivariate gene expression was discovered among replicate samples at the time of amputation and during regeneration (Fig. 6). The different estimates of gene expression among replicates at each time point capture genes as either highly or lowly expressed, *placenta expressed transcript 1* (*plet1*) exhibited a trivariate pattern of expression. We note that expression values for these genes did not co-vary within replicates; thus, it's difficult to attribute these complex expression profiles to age, body size, or sex-related differences among the samples, and we note that all samples were collected at the same time of day. These data show for the first time that genes may exhibit sustained, dynamic regulation under both homeostatic conditions and during limb regeneration. Four (axo24465-r_at, axo31318-r_at, axo31384-f_axo26877-f_at) of 15 bivariate genes are novel to axolotl because they do not align to reference proteins in NCBI databases. The other bivariate genes include: 1) three members of the Ly6/uPAR gene family proteins (*gpibp1*, *psca*, *pinlyp*), 2) a cytochrome p450 (*cyp2a13*), 3) a *Xenopus laevis* lectin (*fucolectin*), 4) a ubiquitin ligase (*herc4*), 5) a sarcoplasmic reticulum Ca(2+)-ATPase (*sln*), 6) a transcription elongation factor (*tcea2*), 7) an immunological cell marker (*mpeg1*), 8) an uncharacterized protein (*c17orf67*), and 9) a cell surface marker (*plet1*) that exhibits a dynamic, biphasic transcriptional profile in providing cues to direct trophoblast stem cell differentiation (Murray et al., 2016). Although the significance of temporally, dynamic expression patterns is unclear, these data suggest a need to consider more than absolute transcript levels when prioritizing candidate genes.

3.4 Genes expressed differently immediately after limb amputation

Many of the genes that were expressed differently between fore and upper arm at the time of amputation were also expressed differently during regeneration. Many additional muscle-associated genes were expressed differently after amputation, as were ECM and cartilage-associated genes that were more highly expressed in fore arms (e.g. *chrdl1*, *umod*, *thdl20*, *matn4*, *lect1*, and *col9a3* in Fig. 5). Considering all 584 genes, the correlation of log2 fold difference between upper and fore arm D0 and DPA0-DPA0.5 samples was $r = 0.87$, and between D0 and DPA1-DPA2 samples $r = 0.67$. Thus, initial gene expression differences between un-amputated fore and upper arms were largely maintained during the early wound healing response. A few signaling pathway genes were more highly expressed in fore arms during this time, including *connective tissue growth factor (ctgf)*, *transforming growth factor beta 2 (tgfb2)*, *fibroblast growth factor receptor like 1 (fgfr1)*, and *dual oxidase 1 (duox1)*, a gene known to participate in appendage regeneration in *X. laevis* and zebrafish (Ferreira et al., 2016; Rieger and Sagasti, 2011; Niethammer et al., 2009).

3.4 Genes expressed differently between 3–9 DPA

Voss et al. (2015) discovered a second pulse of gene expression between DPA2–3 in fore arm samples that was enriched with genes encoding cell cycle proteins. Cell cycle genes were expressed more highly in upper limbs from D0–3 DPA and plateaued at an earlier time relative to fore arm samples (Fig. 7). Thus, not only does muscle tissue appear to be remodeled earlier in upper arms, the transcriptional profiles of cell cycle-associated genes in upper arms suggest an earlier and more robust gene expression response after injury. Although cell proliferation is generally thought to reflect the expansion of progenitor cells during regeneration, transcription of cell cycle genes very early in the wound-healing process may also be associated with the proliferation of immunological cells or epithelial cells that form the wound epidermis. The thin epithelium covering the amputated limb thickens and matures to form a specialized wound epithelium that secretes signaling molecules (e.g. fibroblast growth factors) to stimulate the proliferation of underlying progenitor cells, however this does not occur until 10 DPA (Voss et al., 2015). A more robust cell cycle transcriptional response in the maturing wound epithelium would increase the rate of wound healing in upper arms, especially if this were coupled to metabolic mechanisms that provide energy to fuel cell proliferation. Indeed, *lipase c (lipc)*, a hepatic enzyme that hydrolyzes triglycerides and mediates the uptake of lipoproteins, and a mitochondrial enzyme (*3-hydroxy-3-methylglutaryl-CoA synthase 2 - hmgcs2*) that catalyzes the first step of ketogenesis to provide lipid-derived energy, were expressed more highly in upper arms (Fig. 7).

In addition to cell proliferation, the 3–9 DPA interval is an important preparative phase for subsequent limb bud outgrowth. During this time, damaged tissue and the ECM undergo remodeling. Several tissue remodeling matrix metalloproteinases (MMPs: *mmp1*, *mmp3*, *mmp8*, *mmp10*) exhibited higher expression in fore arms (Fig. 7). MMPs are known to regulate cell-cell and cell-extracellular matrix interactions and were first discovered in amphibians undergoing dramatic tissue remodeling events during metamorphosis (Gross and Lapierre, 1962). Studies of axolotls have demonstrated the necessity of MMPs for successful limb regeneration (Santosh et al., 2011) and mammalian studies have shown that MMPs may

be released by chondrocytes (Bord et al., 1998). Thus, higher expression of MMPs in fore arms (Supplemental File 2) may reflect a relatively higher proportion of chondrocytes and the associated need to remodel relatively more bone tissue to achieve a permissive environment for progenitor cell proliferation. We note that this interpretation may be too simplistic because *ctsk*, an osteoclast-specific cysteine proteinase that is integral to bone remodeling, was expressed more highly in upper arms that contained relatively less overall bone mass. The higher expression of *cathepsin k (ctsk)* may represent another example where transcription is regulated (via osteoclast recruitment or *ctsk* transcription) to be higher in upper arms to facilitate rapid tissue histolysis.

Finally, we note three genes that diverged during the 3–9 DPA interval and maintained expression differences throughout limb regeneration. *desmoglein 4 (dsg4)* is a desmosomal cadherin that mediates cell-adhesion in epithelia, while *avidin (avd)* is a biotin-binding molecule that is highly expressed during newt lens regeneration (Sousounis et al., 2013). Keratin intermediate filaments are key components of the cytoskeleton of cells, but even as they support cellular rigidity and stability, they also perform roles in cell adhesion and migration (Velez-delValle et al., 2016). Four different probe-sets for *keratin 5 (krt5)* exhibited different temporal patterns; sequence comparisons suggest these probe-sets correspond to different axolotl *krt5* paralogs. The expression profile for *krt5-axo06032* showed that it was up-regulated during the 2–3 DPA transcriptional pulse in fore and upper arms, but expression increased more rapidly and achieved higher levels in fore arm samples. *krt5* is a marker of basal and progenitor cells in mammalian epithelial tissue (Knox et al., 2010) and its expression is affected by retinoic acid (see below). We speculate that variation in *dsg4* and *krt5* expression would alter cellular adhesive properties along the proximal-distal axis, conferring different structural identities and properties to cells that might in turn instruct positional information.

3.5 Genes expressed differently at 10 DPA

The 10 DPA time point was identified by Voss et al. (2015) as the most important transition point in the limb regeneration program, marking the time when the limb bud begins to grow out under the influence of proliferating blastema cells. Here we highlight several genes associated with epithelia that were expressed more highly in fore arm samples (Fig. 8). *cathelicidin (camp)* is an epithelial derived peptide which in mammals has multiple innate immune functions including antimicrobial host defense, chemotaxis of immunological cells, and wound repair (Bals et al., 1998). *epiplakin 1 (eppl1)* plays a role in cytoskeletal organization by crosslinking intermediate filaments (e.g. keratins) to microfilaments, microtubules, and cell-adhesion molecules. *epithelial membrane protein 1 (emp1)* has primarily been studied within the context of cancer biology where it is known to affect cell proliferation (Aries et al., 2014). Finally, *keratin 14/17-like* shows identity to vertebrate *krt14* and *krt17*, the latter of which is known to be expressed in axolotl wound epidermis during regeneration (Moriyasu et al., 2012), and in this study, *krt17* was highly up-regulated upon amputation in both fore and upper arms. Both *krt14* and *krt17* have been associated with basal stem cell progenitors in mammalian epithelia (Stellmach et al., 1989). The sustained differential expression of epithelial genes during limb bud outgrowth likely confers different structural properties to proximal versus distal epidermis.

3.6 Genes expressed differently between 18–28 DPA

Two additional pulses of transcriptional change in fore arms were identified by Voss et al. (2015), the first marking the transition from medium bud to late bud (18–20 DPA) and the second marking the transition from late bud (22–24 DPA) to pallet. While genes encoding a variety of functions were identified for the 18–20 DPA pulse, genes from the 22–24 DPA pulse were enriched for cholesterol synthesis, which is required for normal patterning of bone during limb development (Schmidt et al. 2009). Only two cholesterol pathway genes (*squalene epoxidase*, *methylsterol monooxygenase 1*) were expressed differently suggesting conservation of this aspect of limb patterning between fore and upper limbs. We do however note that a few genes identified for the 18–20 DPA (*fos*, *cyr61*, *eppk1*) and 22–24 DPA (*fibroblast growth factor binding protein 1*, *keratin 12*, *prostate stem cell antigen*) pulses in fore arm did not show the same pattern of expression in upper limb. All of these genes were identified as differentially expressed between upper and lower arms at early time points in this study and thus may be informative for understanding persistent proximal-distal cues during regeneration.

We highlight several additional gene expression differences between fore and upper arm samples that were observed between 18–28 DPA. *TRPM8 channel associated factor 1* (*tcaf1*), *leptin* (*lep*), *forkhead box c1* (*foxc1*), and *t-box5* (*tbx5*) were expressed more highly in upper arms samples during this time (Fig. 9). *tcaf1* is a modulator of TRPM8, a calcium ion channel that functions as a cold receptor in mammals. TRPM8 appears to maintain homeostatic conditions in the epidermis by regulating keratinocyte proliferation and differentiation (Bidaux et al., 2016). Studies of zebrafish limb and heart, and axolotl limb regeneration, have shown *lep* to be highly up regulated upon injury (Kang et al., 2016; Voss et al., 2015). We observed a similar up regulation of *lep* in fore and upper arms at 0.05 DPA and then a similar decrease in expression until 10 DPA. However, after this time *lep* decreased linearly in fore arms but levels remained relatively high in upper arms. If *lep* is mitogenic in axolotl, its differential expression between fore and upper arm samples might adjust progenitor cell proliferation relative to the proximal-distal location of amputation. *foxc1*, a forkhead family transcription factor, was also expressed more highly in upper arm samples. Recently, *foxc1* was shown to regulate the terminal differentiation of human keratinocytes (Bin et al., 2016), suggesting yet another potential epithelial difference between regenerating fore and upper limbs. Finally, *tbx5* is a transcription factor that specifies the identity of fore limb cells during limb development and is enriched in axolotl fore limb blastemal tissue during regeneration (Khan et al., 2002). We observed that after amputation, the expression of *tbx5* decreased similarly in fore and upper arm samples, consistent with cellular dedifferentiation. However, higher *tbx5* was observed in upper arm samples after this time, suggesting an earlier specification of fore limb identity in proximal amputations. This is suggestive of a mechanism that may normalize the offset timing of regeneration between fore and upper arm amputations.

Several genes were expressed more highly in fore arm samples, including *cystatin a* (*csta*) and *distal-less homeobox 6* (*dlx6*) (Fig. 8). Interestingly, *dlx6* is expressed in the distal apical epidermal ridge of developing limbs of mice (Robledo et al., 2002) and *dlx6* mRNA is distally enriched in zebrafish caudal fin (Rabinowitz et al., 2017). *csta* is a keratinocyte

protein that plays a role in epidermal development and maintenance, likely through cell-cell adhesion interactions with desmogleins (Gupta et al., 2015). We note that *dsg4* was expressed more highly in fore arms and was identified as retinoic-acid responsive (see below).

3.7 Transcriptional similarities to RA-induced limb proximalization

Retinoic acid administration during the early stages of regeneration reprograms distal blastemas to a proximal state (Maden, 1982). A gene expression analysis using the same microarray in this study was performed recently to identify genes that were expressed during retinoic-acid induced limb proximalization (Nguyen et al., 2017). Of the 533 genes found to be significantly changed in the RA-proximalization study, 43 were also found to be significantly changed in this study (Supplemental File 3). At 20 DPA, the two gene lists showed highly correlated gene expression patterns ($R = 0.82$) with only two genes exhibiting expression in opposite directions. Seven of these genes showed > 2 fold higher expression in upper arm and RA treated samples versus fore arm samples (*aggrecan*, *brevican*, *keratin 19*, *indolethylamine N-methyltransferase*, *tcaf1*, *uroplakin 3a*, and *fatty acid binding protein 2*) and 12 genes with ≥ 2 fold lower expression in upper arm and RA treated samples versus fore arm samples (2 probes with no annotation, *toll like receptor 2*, *dsg4*, *gap junction protein beta 6*, *prolactin releasing hormone*, *riddle 2*, *protein phosphatase 1 regulatory inhibitor subunit 14C*, *krt14/17-like*, *krt5*, *transglutaminase 1*). Interestingly, none of these genes is a transcription factor and most are associated with cell stiffness, cell migration, epithelia, and ECM components. This supports the idea that proximal and distal blastema cells have different cell adhesion properties (Nardi and Stocum, 1983; Crawford and Stocum, 1988) and further emphasize the strong signal of epithelial and ECM differences identified in this study.

4. Conclusions

We identified genes that were expressed differently between regenerating upper and lower arms using two highly powered gene expression datasets. We reasoned that differently expressed genes might reveal mechanisms underlying the difference in regenerative rate between proximal and distal amputations, and positional information in cells during limb regeneration. We discovered early gene expression differences that suggest upper arms undergo more robust tissue remodeling and cell proliferation responses after amputation. These differences provide an explanation for why the overall time to complete regeneration is similar for proximal and distal amputations. Later in the regeneration program we identified genes that may contribute to proximal-distal differences in regeneration rate through their effects on cell proliferation and differentiation. The differently expressed epithelial proteins discovered between fore and upper arm samples predicts proximal-distal variation in the structure and function of the wound epidermis. Finally, we identified dynamic, bivariate transcriptional patterns of genes, some of which have unknown functions in amphibian epithelia or are predicted to contribute gelatinous and filamentous components to the ECM during regeneration. These complex patterns of gene expression implicate transcriptional control as a property that not only explains regenerative rate differences between proximal and distal locations of the limb axis but may also directly or indirectly

inform positional information among local progenitor cells. To understand the significance of transcriptional control during salamander limb regeneration will likely require even finer temporal and spatial sampling.

Fig. 1. Cartoon showing stages of limb regeneration relative to time after amputation, and an overview of the experimental design.

Fig. 2.

Histology of axolotl forearm and upper arm. (A) Tissue was collected from intact limbs at the same position that tissues were collected for microarray analysis of upper and fore arms. Red staining indicates muscle staining and blue indicates nuclear staining. Green fluorescence seen in A is fragmented calcified bone, as calcified bone exhibits auto-fluorescence in the green channel. Osteocytes were identified and bone area was calculated by histological identification. Skeletal structures and muscle was traced and calculated as a percentage of the total area using ImageJ. Calculated area is represented as corresponding colors in the figure legend. (B) Calculated area (n=4) distribution for each limb sampled. Samples passed a Levine's test for equal variance and only the area of bone was significantly different between fore and upper limbs using a student's T test with equal variance ($p=0.021$).

Fig. 3.

Example expression profiles for muscle-associated genes that were expressed differently between fore (orange) and upper (blue) arm samples at the time of amputation and during the first 10 days of regeneration. Error bars are standard deviations of the mean.

Fig. 4.

Gene expression profiles for early immediate genes (*klf2*, *cyr61*, *fos*, *egr1*) and two transcription factors (*meis2*, *hoxa13*) that were expressed differently between fore (orange) and upper (blue) arm samples during regeneration. Of these genes, only *klf2*, *fos*, and *cyr61* exhibited a 2-fold expression difference at one or more of the time intervals investigated. See Supplemental File 2 for the specific intervals of time that genes were expressed differently. Error bars are standard deviations of the mean.

Fig. 5.

Gene expression profiles for some of the extracellular matrix-associated genes that were expressed differently between fore (orange) and upper (blue) arm samples at the time of amputation and during regeneration. See Supplemental File 2 for the specific intervals of time that genes were expressed differently. Error bars are standard deviations of the mean.

Fig. 6.

Gene expression profiles for some of the genes that showed bivariate (*pinlyp*, *psca*), and in one case trivariate (*plet1*), expression profiles. The left panels show the mean expression values for fore (orange) and upper (blue) arm samples throughout regeneration. Error bars are standard deviations of the mean. The right panels show expression values obtained from each replicate microarray.

Fig. 7.

Example expression profiles for cell-cycle (*pcna*, *mki67*), lipid metabolic (*lipc*, *hmgcs2*) and matrix metalloproteinase (*mmp1*, *mmp10*) genes that were expressed differently between fore (orange) and upper (blue) arm samples for the 3–9 DPA time interval. Error bars are standard deviations of the mean.

Fig. 8.

Example expression profiles for epithelia-associated genes that were expressed differently between fore (orange) and upper (blue) arm samples at 10 DPA. See Supplemental File 2 for the specific intervals of time that genes were expressed differently. Error bars are standard deviations of the mean.

Fig. 9.

Example expression profiles for genes that were expressed differently between fore (orange) and upper (blue) arm samples for the 18–28 DPA time interval. See Supplemental File 2 for the specific intervals of time that genes were expressed differently. Error bars are standard deviations of the mean.

Table 1

Gene Ontology and Pathway terms that were significantly enriched using all genes that were differentially expressed between fore and upper arm samples.
