## **STUDENT AGREEMENT:**

I represent that my thesis or dissertation and abstract are my original work. Proper attribution has been given to all outside sources. I understand that I am solely responsible for obtaining any needed copyright permissions. I have obtained needed written permission statement(s) from the owner(s) of each third-party copyrighted matter to be included in my work, allowing electronic distribution (if such use is not permitted by the fair use doctrine) which will be submitted to UKnowledge as Additional File.

I hereby grant to The University of Kentucky and its agents the irrevocable, non-exclusive, and royalty-free license to archive and make accessible my work in whole or in part in all forms of media, now or hereafter known. I agree that the document mentioned above may be made available immediately for worldwide access unless an embargo applies.

I retain all other ownership rights to the copyright of my work. I also retain the right to use in future works (such as articles or books) all or part of my work. I understand that I am free to register the copyright to my work.

## **REVIEW, APPROVAL AND ACCEPTANCE**

The document mentioned above has been reviewed and accepted by the student's advisor, on behalf of the advisory committee, and by the Director of Graduate Studies (DGS), on behalf of the program; we verify that this is the final, approved version of the student's thesis including all changes required by the advisory committee. The undersigned agree to abide by the statements above.

## ABSTRACT OF THESIS

### “THE TALE OF 3,000 ZIRCONS”: AN INVESTIGATION OF GRENVILLE SEDIMENTATION IN AMAZONIA USING U/PB DETRITAL ZIRCON GEOCHRONOLOGY

The continental collision between Laurentia and Amazonia that generated Rodinia and the Grenville Orogen is proposed to be one of the largest, hottest and longest-lived orogens in Earth history. Subsequent erosion and weathering led to a mountain range's worth of sediment recycled into clastic systems across North America, otherwise known as the “Great Grenville Sedimentation Event”. The Sunsas orogeny in Amazonia is correlative to the Grenville in North America and is proposed to be the result of final Rodinian collision at 1200-1000 Ma. Despite the connection between the two ranges and the robust sedimentary record in North America, little work has been done to constrain sediment availability on the Amazonian side of the Grenville orogen. This study examined 16 samples collected from western Brazil including quartz-arenite, diamictite, quartzite, and other metasedimentary units, with basement samples for age comparison. Detrital zircons were analyzed for U/Pb isotope ratios using LA-ICP-MS, resulting in approx. 3,000 analyses for the 16 samples. These analyses suggest only a minor sediment contribution to the Amazonian craton from Grenville-age terranes. Instead, most samples exhibit ages characteristic of Amazonian Precambrian basement. The dominance of Geons 15 and 17 indicates that Grenville-aged sediment does not constitute the main sediment-source region and with no significant increase in the number of Grenville zircons in samples collected proximal to the Sunsas orogenic front. We interpret these results to mean that although Laurentian clastic sequences are perpetually dominated by Shawinigan and Ottawan sources, the Amazonian craton was not influenced by the same sediment influx.  $^{40}\text{Ar}/^{39}\text{Ar}$  analyses from southwest Amazonian document a change in tectonic regime during the Grenville cycle, transitioning from collisional, thrust-dominated along the Laurentian margin to strike-slip in Amazonia. The lack of Grenville-aged sediment supports an asymmetric orogen in which changes in crustal thickness and exhumation prevented erosion and deposition on the Amazonian side making the primary source for sediments the Amazonian tectonic provinces.

## ACKNOWLEDGMENTS

I would like to say how grateful I am to Dr. Dave Moecher for taking a chance on me and giving me the opportunity to work with him the last two years on this thesis. Dr. Moecher's instruction, expertise, and constructive criticism has been invaluable and helped me grow as a scientist and a person. I would also like to say thank you to my committee members, Dr. Ryan Thigpen and Dr. Mike McGlue for their support and patience over the duration of the project. I would also like to acknowledge Dr. Eric Tohver from the University of São Paulo for escorting Dr. Moecher and I around western Brazil to collect samples during our trip in June 2019.

This thesis project would not have been possible without funding from the Geological Society of America Student Research Grant, NSF grant 1551342 for acquisition of the UK JEOL IT-100 SEM and NSF grant 1624663 for support in acquisition of detrital zircon age data. Travel for this project was only made possible by the generous grants from the Department of Earth and Environmental Sciences Ferm Fund and Brown-McFarlan fund here at the University of Kentucky.

Finally, I would like to say a very heartfelt thank you to my friends and family, especially Aaron Ashley. Thank you for patiently listening to me talking about zircons and the Grenville orogen for two years. Thank you for reading all my drafts and helping me when I could not figure something out in Excel and Illustrator. Thank you for traveling back and forth the last two years to provide moral support over the duration of this work, without you I never would have made it through this, I love you.

## CHAPTER I: INTRODUCTION

The deposition of syn- to post-orogenic sediments represents a crucial phase in the history of a collisional orogen and the development of its characteristic, adjoining flexural foreland basins (Quinlan and Beaumont, 1984; Stockmal et al., 1986; Klein and Hsui, 1987; Beaumont et al., 1988). Interpretations of the interactions between dynamic mechanisms that drive sediment distribution can be used to establish provenance, elucidate previous tectonic settings and collisional histories, and reconstruct paleogeography. Establishing provenance is critical to understanding how sediment in large orogens is distributed and reworked over time (Dickinson and Suczek 1979; Dickinson et al., 1983; Rainbird et al., 2012). However, determining provenance from clastic sediment presents particular challenges in establishing the original protolith due to travel distance from the source, weathering along the sediment path, multiple phases of recycling, and reworking of sediments before deposition (Blatt 1967; Veizer and Jansen, 1979; Dickson and Suczek 1983; Dickinson et al., 1983; Pettijohn et al., 1987; Johnsson, 1993; Cox and Lowe, 1995; Garzanti, 2016; Moecher et al. 2019).

The Grenville Orogen (1.3-0.9 Ga) is proposed to be one of the largest, hottest and longest-lived orogens in Earth history (Beaumont et al., 2010). The “Great Grenville Sedimentation Episode” (GGSE: Rainbird et al., 2012) is the continental-scale clastic system across Laurentia produced by the Grenville Orogeny. As such it should have generated a mountain range’s equivalent of sediment, which was subsequently distributed and reworked across the Laurentian craton. The unusual longevity (ca. 400 m.y.) and hot geothermal conditions that characterized the Grenville Orogeny resulted in “hot granites” (Miller et al., 2003; Moecher et al., 2014; Samson et al., 2019) with high Zr contents that

produced an unusually high number of zircons, which, upon exhumation and erosion, were subsequently recycled throughout the sedimentary record into the various Phanerozoic clastic systems spanning the North American continent (Eriksson et al., 2004; Thomas et al., 2004; Becker et al., 2006; Moecher and Samson 2006; Park et al., 2010; Moecher et al., 2019, 2020). These studies repeatedly show the presence of Grenville zircons and, by extension, Grenville sediment, typified by the recurring Grenville age doublet produced by the Shawinigan and Ottawan phases (ca. 1.2 and 1.0 Ga) (Fig. 1.1). The well-defined age doublet in Phanerozoic sediments across Laurentia indicates that post-Grenville sediments were recycled over the geologic record and continue to persist and be recycled (Eriksson et al., 2003, 2004; Mueller et al., 2008; Rainbird et al., 2012; Moecher et al., 2019, 2020) (Fig. 1.2).

Although the Grenville detrital zircon age signature is well documented in North American clastic sequences, the sedimentary record of the Grenville orogeny on the Amazonian side of the orogen is much less clear. The Sunsás Orogeny (1250-980 Ma) represents the youngest Meso-Neoproterozoic collisional event between Amazonia and Laurentia along the southwest margin of the Amazonian craton (Santos et al., 2000; Santos et al., 2002; Tohver et al., 2002; Boger et al., 2005; Cordani and Teixeira 2007; Fuck et al., 2008; Cordani et al., 2009; Teixeira et al., 2010). Despite the widespread distribution of Grenville-aged terranes in western South America and their potential relationship to the Laurentian Grenville (Tosdal 1996; Tohver et al., 2002; Loewy et al., 2003; Tohver et al., 2006; Cordani and Teixeira 2007; D'Agrella-Filho and Tohver 2008; Fisher et al. 2010; Brito Neves et al., 2014), previous DZ geochronology for earliest post-orogenic sediments appears to lack the prominent age peaks associated with the post-

orogenic Grenville sedimentation observed in Laurentia. Rather, Amazonian DZ age spectra exhibit significantly older age modes compared to Laurentian clastics, with little evidence for a major Grenville-sourced component (Santos et al., 2000; Fuck et al., 2008; Santos et al., 2008; Cordani et al., 2009).

In addition to potential differences in syn- to post-Grenville clastic sequences, differences exist in the “crustal provenance” of basement terranes that comprise the Grenville orogen in Laurentia. Previous geochemical, geochronologic, and geologic mapping in the southern Appalachians concluded that the Blue Ridge is allochthonous and exotic to the Laurentian craton and Grenville basement terranes. Pb isotope compositions of Grenville basement rocks of the central and southern Appalachians (Sinha et al., 1996; Fisher et al., 2010) are distinctly different (higher  $^{207}\text{Pb}/^{204}\text{Pb}$  for any  $^{206}\text{Pb}/^{204}\text{Pb}$ ) than basement rocks of the Grenville Province in Ontario (DeWolf and Mezger 1994), Adirondacks (Sinha 1996, McLelland et al., 2013), and Llano province (Tohver et al., 2002, Loewy et al., 2003), and of the Granite-Rhyolite Province (Fisher et al., 2010), having Pb isotope values that are more like Amazonia (Lowey et al., 2003; Tohver et al., 2006) (Fig. 1.3). Nd depleted mantle model extraction ages ( $T_{\text{DM}}$  ages) for the southern and central Blue Ridge range from 1.6 to 2.0 Ga (Carrigan et al., 2003; Fisher et al., 2010), i.e., they are much older than their zircon U-Pb crystallization ages, consistent with an origin from reworking of older crustal material (i.e., they are not juvenile). Similarly, rocks of the Amazonian craton also yield  $T_{\text{DM}}$  ages ranging from 1.6-2.2 Ga (Neves et al. 2014, Santos et al. 2008, Cordani et al. 2007, Tohver et al. 2004). However,  $T_{\text{DM}}$  ages for native Laurentian basement rocks are the same as or only slightly older than their U-Pb crystallization ages, i.e., they are juvenile. The similarity of Pb and

Nd isotope systematics suggest that the southern Blue Ridge was transferred to Laurentia during Grenville orogenesis and consistent with the Amazonian transfer hypothesis (Santos et al., 2000, Tohver et al., 2006, Rizzotto et al., 2014). Since Laurentia and Amazonia were paleogeographically linked during Grenvillian collision there might be a Laurentian Grenville detrital zircon signature within syn- to post-Grenville sedimentary sequences across Amazonia, i.e., there might be an equivalent GGSE apparent across Amazonia.

This study will address via detrital zircon provenance analysis the following questions related to Laurentian-Amazonian collision and Rodinian assembly:

- To what extent was Grenville sediment deposited onto the Amazonian craton?
- Is there evidence of the Grenville “doublet”, commonly observed in North American clastic sequences, in Amazonian?
- What does the presence or absence of Grenville-aged detrital zircons imply about the nature of the tectonic boundary between Amazonia and Laurentia during Rodinian assembly?
- How does exhumation rates of the Grenville orogen vary in Amazonia versus Laurentia?

Figure 1.1. Zircon U-Pb crystallization age for Grenville Appalachian Inliers, Adirondacks, and the central to eastern Laurentian basement magmatic and metamorphic age distributions from zircon U-Pb Sensitive High-resolution Ion Microprobe (SHRIMP) analyses (Moecher et al., 2018).

## CHAPTER II: GEOLOGIC SETTING

The southwest margin of the Amazonian craton in western Brazil and eastern Bolivia records the collision between Amazonia and Laurentia during the Mesoproterozoic amalgamation of Rodinia. Much like the eastern margin of Laurentia, the Archean to Proterozoic Amazonian craton expanded through a series of crustal accretionary events trending NW-SE (present coordinates) that young towards the southwest (Teixeira et al., 1989; Tassinari and Macambira, 1999; Tassinari et al., 2000; Tohver et al. 2005; Boger et al. 2005; Santos et al. 2008). Four tectonic provinces comprise the western margin of the craton: Ventuari-Tapajós (1950–1800 Ma), Rio Negro-Juruena (1800–1550 Ma), Rondônia-San Ignacio (1450–1300 Ma), and Sunsás-Aguapeí (1250–1000 Ma) provinces (Teixeira et al., 1989; Boger et al., 2005; Cordani and Teixeira, 2007; Bettencourt et al., 2010) (Fig. 2.1 and 2.2). The deformation and magmatic history of the region remains enigmatic; however, it is commonly accepted that younger accretionary belts represent continental margin arcs built upon the preexisting basement domains (Boger et al. 2005; Geraldes et al., 2001; Tassinari and Macambira, 1999).

Litherland et al. (1986, 1989) proposed that the Sunsás Orogenic cycle encompassed metasediments and plutonic rocks between 1280-980 Ma exposed in eastern Bolivia and western Brazil (Santos et al., 2008). Litherland (1986) limited the timing of the Sunsás orogeny between 1000-950 Ma in Amazonia, making it coeval with the final two phases of the Grenville Orogenic cycle (Ottawan and Rigolet) (McLelland

et al., 2013) in Laurentia. The Sunsás orogenic cycle deformation is related to three mobile belts in southwestern Amazonia: Sunsás, Nova Brasilândia, and the Aguapeí belt (Teixeira et al., 2010; Santos et al., 2008; Boger et al., 2005). Samples for this study were collected from each of the Amazonian mobile belts and will be discussed in further detail below.

### ***Sunsás Belt***

The Sunsás province encompasses an exposed area of approximately 350,000 km<sup>2</sup> in western Brazil and neighboring Bolivia (Fig. 2.2). Early Sunsás group sediment deposition occurred ca. 1250-990 Ma in an alluvial to deltaic passive margin environment and was subsequently metamorphosed by late Mesoproterozoic orogenic events (Santos et al., 2011; Boger et al., 2005; Saes et al., 1992; Litherland and Bloomfield, 1981). The Sunsás group reached a thickness of 6 km and is comprised of a basal conglomerate overlain by two psammitic units (arkoses, sandstones, quartzites) and an interbedded pelitic unit (argillaceous mud and siltstones) (Santos et al., 2011; Santos et al., 2008; Boger et al., 2005; Berrangé and Litherland, 1982). Deformation of the Sunsás group sediments occurred during a late Mesoproterozoic-Neoproterozoic collisional orogenic event and the deformed sediments were intruded by syn- to late-tectonic granites and post-tectonic anorogenic plutons during the late Mesoproterozoic and early Neoproterozoic (1100-980 Ma) (Boger et al., 2005; Cordani and Teixeira, 2007).

### ***Nova Brasilândia Belt (RO-8, RO-9, RO-10)***

The Nova Brasilândia metasedimentary belt in southern Rondônia (Fig. 2.2) is comprised of metamorphosed deep-water sediments deposited ca. 1211-1110 Ma

(carbonates intercalated with fine-grained pelitic and sandy units and turbidites) (Rizzotto, 1999; Santos et al., 2000; Tohver et al., 2004; Boger et al., 2005; Cordani and Teixeira 2007; Teixeira et al., 2010). The group was metamorphosed to upper amphibolite to granulite facies and intruded mafic dykes, sills and felsic plutons that are coeval to late Neoproterozoic Sunsás intrusions. The Nova Brasilândia belt depositional environment has been interpreted as: an intracontinental rift setting followed by the opening of a proto-ocean that was subjected to crustal shortening, deformation, and magmatism (Rizzotto et al., 2014; Rizzotto 2001; Rizzotto 1999) or as the result of transpressive suturing of the Amazonian and Paraguá cratons leading to crustal thickening through imbrication during the final stages of Rodinian assembly (Tohver et al., 2004, 2005).

#### ***Aguapeí Belt (MT-4, MT-13)***

The Aguapeí belt is a restricted metasedimentary belt approximately 500 km long in the southwestern portion of the Mato Grosso state (Fig. 2.2). It is comprised of the folded metasedimentary Aguapeí group deposited ca. 1167-1149 Ma in an aulacogen or rift environment (Rizzotto et al., 2014; Santos et al. 2005; Saes 1999; Saes et al., 1992). The Aguapeí group is a sequence of siliciclastic rocks composed of conglomerates, quartz sandstones, interbedded metapsamites, and fluvial sandstones and siltstones (Souza and Hildred, 1980). The Aguapeí group was affected by sub-greenschist-facies metamorphism and localized deformation resulting in gentle folds and shearing of the rocks which are evident in recrystallized mylonites (e.g., Teixeira et al., 2010; Tohver et al., 2004; Ruiz 2005; Geraldés et al., 2001).

## **Sedimentary Units**

### ***Dardanelos Formation (RO-6, RO-7, RO-9)***

The Dardanelos Formation crops out approximately 900 km within the Rio Negro–Juruena province from northwest Mato Grosso into central Rondônia. It is part of the early Mesoproterozoic (Ectasian) Caiabís graben (Santos et al., 2000; Leite and Saes, 2003; Cordani and Teixeira 2007). The Dardanelos Formation encompasses several regionally distributed units of juvenile volcano-sedimentary origin ca. 1.5–1.4 Ga., each with similar but slightly different lithologies. For this study, the term Dardanelos Formation is used for classification of samples RO-6, RO-7, and RO-9 in eastern Rondônia (Fig. 2.3A). Basement intrusives associated with the formation are rapakivi granite, monzogranites, charnokite, mangerite, and mafics. Sedimentary units overlying the basement units are comprised of fluvial arkose sandstones, conglomeratic sandstones, and siltstones.

### ***Pimenta Bueno Formation Diamictite (RO-12)***

The Pimenta Bueno formation lies within the Parecis Basin, an intracratonic, rift-sag basin, formed during extensional events following the Rodinia break up (1000–750 Ma) (Pedreira and Bahia, 2000). The Pimenta Bueno Formation (Fig. 2.3A) is composed of siliciclastic and carbonate rocks with an estimated thickness of 250 m (Afonso and Nogueira 2018). The basal polymictic diamictite unit is composed of clasts of quartz, granitoids, volcanics, and gneiss fragments ranging from a few centimeters up to 1 m in a red/purplish matrix (Gaia et al., 2017). The diamictites were deposited during a

transgressive system from rainouts of icebergs in a glacial marine environment during the latest Neoproterozoic, ca.622 Ma (Afonso and Nogueira 2018).

***Cuiabá Group and Puga Formation (Diamictites MT-3, MT-15)(Conglomeratic Sandstone MT-14)***

The Cuiabá Group and Puga Formation of the northern Paraguay belt in the Cuiabá region of western Mato Grosso (depositional age ca. 635-590 Ma) contains a thick sequence of glaciomarine, turbidite, carbonate, and siliciclastic sedimentary rocks formed in an extensional continental margin platform facies (Alveranga et al., 2011; Alvarenga and Trompette 1992). The Puga formation is a massive glaciomarine diamictite around 100 m thick overlying Paleoproterozoic basement. The diamictite contains stratified clasts ranging from cobble to boulder in size commonly comprised of basement clasts of granite, intermediate volcanic, quartzite, sandstone, and schist in an iron-rich red clay matrix (Fig. 2.3B) (Alveranga et al., 2011; Alvarenga and Trompette 1992).

The Puga Formations passes latterly into the Cuiabá Group which includes a thick sequence of fine-grained sandstone, siltstone, conglomerate, and diamictite. The depositional environment of the Cuiabá Group is deep glaciomarine slope and outer slope (Alveranga et al., 2011; Alvarenga and Trompette 1992). Conglomeritic sandstones grading into fine-grained sandstones are common within this unit. Pebbles of quartz, feldspar, and schist within the sandstones are 1 cm to 10 cm in diameter.

### ***Raizama Formation (MT-2)***

The Raizama Formation (depositional age 600-542 Ma) occurs at the base of the Alto Paraguai Group in western Mato Grosso. The Alto Paraquai is a group of glacial, platform, tidal-, wave- and storm-dominated shoreline, fluvial and deltaic depositional systems associated with changes in sea-level from global glaciation events in the late Neoproterozoic (Nogueira and Riccomini 2001; Bandeira et al., 2007; McGee 2013). The Raizama Formation (Fig. 2.3B) is comprised of a siliciclastic sequence of fine to medium-grained sandstone, cemented by dolomite, with hummocky crossbedding, ripple marks, and rip up clasts, interpreted as a storm and tidal influenced littoral deposit (Nogueira and Riccomini 2001; Silva et al., 2007; McGee 2013).

### ***Furnas Formation (MT-1)***

The Devonian Furnas Formation is part of the Paraná Basin, a wide intracratonic basin that covers approximately 1,700,000 km<sup>2</sup> of southeast South America, 1,100,000 km<sup>2</sup> of which is in Brazil. The Furnas Formation (Fig. 2.3B) is predominantly comprised of braided stream deposits interpreted to have been the result of the outwash of a periglacial fringe that accumulated during a regression ca. 395-360 Ma (De Ros 1998; Zalan et al., 1987). The formation is composed of fining-upward, crossbedded, quartz arenites interbedded with pebbly sandstones (De Ros 1998; Zalan et al., 1987).

## CHAPTER III: ANALYTICAL METHODS

### *U-Pb Zircon Geochronology*

Fifteen representative samples were collected from Amazonia in the western states of Mato Grosso and Rondônia in Brazil. 12 samples were analyzed using detrital zircon methods and the remaining three were prepared and treated as igneous samples. Prior to analysis the samples were prepared at the University of Kentucky. Approximately 3-5 kg of each sample was crushed into 2-4 mm gravel-sized fragments using the jaw crusher and then ground to fine to medium-grained sand using the disk mill. Equipment was cleaned using compressed air, wire brushes, and isopropyl alcohol between each sample to avoid contamination. The samples were then dry and wet sieved using disposable plastic mesh screens with size intervals of 250, 125, and 53  $\mu\text{m}$  to remove clay-sized particles. The remaining 250-125  $\mu\text{m}$  and 125-53  $\mu\text{m}$  size-fractions for each sample were washed in ultrasonic bath and dried in ovens overnight. Magnetic minerals were removed using a ceramic block magnet. Heavy minerals were separated from the sands using acetylene tetrabromide (specific gravity (SG) = 2.96) and methylene iodide (SG = 3.32). Magnetic minerals remaining in the sample were removed using a Frantz Isodynamic Magnetic Separator Model LB-1 at increasing current up to 1.5 Amps resulting in a relatively pure zircon aliquot. Zircons from the 53–125  $\mu\text{m}$  aliquot were then selected to be mounted in epoxy for U-Pb dating due to a much higher abundance of zircons when compared to the 125-250  $\mu\text{m}$  size fraction.

Zircon mounts were prepared for assessing hundreds of grains for U-Pb age-dating. A 1" diameter plastic mold was affixed to a 2x2" square of doubled sided tape, zircon concentrate was poured into a 0.5 x 0.5 cm brass tube and rotated and tapped to ensure even distribution. Three separate samples (four individual mounts) were placed within each one-inch mold along with zircon standards FC-1, SL-mix, and R33, ensuring adequate space between the samples and standards. For the three igneous samples in this study 35-50 prismatic zircon grains were handpicked from their aliquots and individually placed in rows on a separate mount along with standards. Additionally, precautions were taken to ensure no cross-contamination between the samples. An epoxy was mixed using five parts Buehler Epo-Thin epoxy resin with two parts Buehler Epo-Thin epoxy hardener and poured into the mounting ring and left to cure for at least 24 hours. The epoxy mounts were then sanded down using 1500 and 2000 grit sandpaper, followed by a 0.3  $\mu\text{m}$  alumina powder polish.

Backscatter electron (BSE) and cathodoluminescence (CL) images were collected on the University of Kentucky's CAMECA SX50 electron probe microanalyzer and the JEOL IT-100 scanning electron microscope (SEM). The images collected were used to identify the presence of xenocrysts, zoning, inclusions, fractures, and metamorphic overprinting within individual zircon grain. The images collected were used as a guide to target ideal spots for LA-ICP-MS analyses.

Zircons were dated at the University of Arizona LaserChron Center using laser ablation-inductively coupled plasma-mass spectrometry (LA-ICP-MS) on a Thermo Element2 multicollector ICP-MS. Operating conditions used for data collection are described by Gehrels et al.,(2008). Approximately 300 grains were analyzed for each

sample. Zircon standards Sri Lanka (~563 Ma), FC-1 (~1099 Ma), and R33 (~419 Ma) were analyzed every five grains. In each analysis zircon grains were ablated with a Photon Machines Analyte G2 excimer laser equipped with a HelEx ablation cell with a spot diameter of 20  $\mu\text{m}$ . The ablated material was transported by helium to the Element2 ICP-MS. The analysis processes involved 5 seconds of measuring peaks with a non-firing laser in order to collect relative background intensities and was then followed by 10 seconds of measuring peaks with the firing laser. The system then performed a 20 second delay in order to purge the system of ablated material between each analysis. Raw U-Th-Pb data reduction was performed at the University of Arizona using a Python decoding routine and the Excel program “E2agecalc” to calculate concentrations, isotopic ratios, and ages for unknowns. U-Pb Concordia, Tera-Wasserburg, weighted mean, and probably density plots were created using Isoplot 4.15 (Ludwig, 2011).

## CHAPTER IV: RESULTS OF U-PB ZIRCON GEOCHRONOLOGY

Analyses from visible cores in zircon grains ranging in size from 53  $\mu\text{m}$  to 125  $\mu\text{m}$  separated from Amazonia Paleoproterozoic (MT-5), Mesoproterozoic (MT-4, RO-6, RO-7, RO-9, RO-11, MT-13, RO-10), Neoproterozoic (MT-3, MT-14, MT-15, RO-8, and RO-12), and Paleozoic (MT-1, MT-2) formations (Table 4.1) were used to determine: (1) potential age populations of source rocks that correspond to specific magmatic or metamorphic zircon generating events i.e. Grenville or Amazonian and (2) provide constraints on the maximum depositional age of the sedimentary protolith. Magmatic zircon cores were analyzed to determine igneous protolith age and used for comparison to detrital Amazonian age-modes obtained from the analyses. Geochronologic data including raw isotopic ratios and U-Pb ages are compiled in Appendix 1. The “best ages” used to compile histograms were determined from  $^{206}\text{Pb}/^{238}\text{U}$  ages for grains less than 900 Ma and  $^{206}\text{Pb}/^{207}\text{Pb}$  ages for grains greater than 900 Ma. This distinction is made because  $^{206}\text{Pb}/^{238}\text{U}$  ages are more precise for dates < 900 Ma and  $^{206}\text{Pb}/^{207}\text{Pb}$  ages are more precise for older dates (Gehrels, 2008).

Discordancy of the U-Pb system is a common phenomenon occurring in zircons analyzed by LA-ICP-MS. Explanations for the observed discordancy include lead loss due to zircon recrystallization or high-grade metamorphic events, or as a result of laser spot analyses overlapping zircon growth zones. Probability density plots and histograms used only zircon analyses that are 95-105% concordant. The most probable age modes and minor peaks for each sample were calculated using the “Unmix” function in Isoplot. Protolith ages for magmatic zircons were calculated and plotted using Wetherill and Tera-Wasserburg concordia diagrams.

## ***Paleoproterozoic***

### ***MT-5***

MT-5 had 315 grains analyzed, and 275 grains were 95-105% concordant (Fig. 4.3A). Zircon grains in MT-5 are anhedral to euhedral and very angular to subrounded. Most of the grains exhibit strong oscillatory zoning and an absence of unzoned rims, typical of magmatic zircons (Fig. 4.3B-D). Many zircons were fractured and avoided for analysis. Zircons from MT-5 plot along or near concordia in a linear array and exhibit a dominant age mode of 1832 Ma and two minor age modes at 1890 Ma and 2005 Ma (Fig. 4.3A). Two single grains at 1100 Ma and 1232 Ma are interpreted to be the result of contamination during sample preparation.

## ***Mesoproterozoic***

### ***MT-4***

The MT-4 sample was collected from the eastern flank of the Aguapeí mobile belt had 315 grains analyzed with 215 grains between 95-105% concordant (Fig. 4.4A). Most zircon grains are anhedral to subhedral, with some euhedral grains and angular to rounded. Many of the zircon grains are fractured and broken but most display magmatic oscillatory zoning observed in CL imaging (Fig. 4.4B-D). Most grains are heterogeneous displaying a variety of zoning patterns, variations in brightness, and lack of rim overgrowths. Most analyses for MT-4 plot in a linear fashion along the concordia line but discordance is present in a number of the grains. MT-4 has two dominant age modes; 1542 and 1781 Ma (Fig. 4.4A). Two single concordant zircon grains from the sample yield ages of 1255 and 1261 Ma.

### ***RO-6***

Sample RO-6, a Mesoproterozoic monzogranite, was collected in eastern Rondônia and analyzed as a magmatic sample. 35 zircons were analyzed and 17 were used for age determination based on concordancy. Most zircons were subhedral to euhedral and all display oscillatory zoning around cores. Several of the zircons contain xenocrysts and appear to have overgrowth rings around the rim. Single spot  $^{206}\text{Pb}/^{238}\text{U}$  ages range from 1525-1563 Ma. The concordia diagram (Fig. 4.11A) shows discordancy in many of the analyses but concordant ages are generally within error. The calculated upper intercept for the sample is at  $1550 \pm 15$  Ma and the lower intercept has a large error and does not correspond to a known geologic event.

### ***RO-7***

RO-7 was collected from the Dardanelos Formation directly overlying basement sample RO-6. 315 zircon grains were analyzed from the sample, 63 analyses were discarded from final totals due to anomalous  $^{204}\text{Pb}$ . Of the 252 remaining analyses, 115 were strongly discordant, plotting below concordia in a sublinear array, leaving 137 analyses 95-105% concordant (Fig. 4.5A). Most zircon grains are anhedral to subhedral however a small portion of grains are euhedral. Most of the grains show oscillatory (sometimes faint) or sector zoning and lack overgrowths (Fig. 4.5B-D). Two age modes dominate samples RO-7: 1548 Ma and 1776 Ma (Fig. 4.5A), with no concordant grains younger than 1514 Ma. The four oldest grains in the sample yield dates of 2125, 2157, 2197, 2210 Ma.

### ***RO-9***

Sample RO-9, a charnokite basement orthogneiss was analyzed using single spot analysis on 35 grains. Zircon grains are euhedral and acicular and display very bright oscillatory zoning characteristic of magmatic zircons.  $^{207}\text{Pb}/^{206}\text{U}$  ages range from 1455-1552 Ma with slight discordance (Fig. 4.11B). An upper intercept of  $1518 \pm 16$  Ma is interpreted as the crystallization age of the orthogneiss protolith. The lower intercept of  $1012 \pm 280$  Ma is consistent with Pb loss or growth of a new generation of zircon during Sunsas high-grade metamorphism.

### ***RO-11***

Sample RO-11, a granulite facies paragneiss from the Nova Brasilândia metasedimentary belt in central Rondônia. Zircon grains are euhedral to subhedral and display moderate oscillatory zoning. Although the sample is a paragneiss, only a small number of detrital zircons were analyzed. Single spot  $^{207}\text{Pb}/^{206}\text{U}$  ages range from 984-1528 Ma (Fig. 4.11C) Concordia diagram shows variable discordancy, with an upper intercept of  $1427 \pm 27$  and a lower intercept of  $1049 \pm 58$  (MSWD = 2.7) consistent with Pb loss or growth of a new generation of zircon during Sunsas high-grade metamorphism (Fig. 4.11C).

### ***MT-13***

The MT-13 sample was collected from the western Aguapeí belt in western Brazil along the Bolivian border and had 315 grains analyzed with 281 grains between 95-105% concordant (Fig. 4.6A). Most of the zircons are angular to subrounded and subhedral to euhedral however, there is a large abundance of anhedral grains that are very well-rounded. Most grains exhibit oscillatory and sector zoning. Several zircons contain xenocrysts and overgrowth rims (Fig. 4.4B-D). Many of the zircons are broken and show fractures on the surface. Zircon grains from MT-13 plot along or near concordia and yield two primary age modes at 1350 and 1410 Ma (Fig. 4.6A). Two smaller age modes are also present at 1522 Ma and 1764 Ma.

### ***RO-10***

Sample RO-10 was collected from the Nova Brasilândia metasedimentary belt. 315 zircon grains were analyzed and 216 were 95-105 % concordant (Fig. 4.7A). Discordant analyses excluded from “best age” modes were highly discordant, falling below concordia in a sublinear manner. Grains are anhedral to subhedral and angular to well-rounded, with very few euhedral grains. Zircons typically show oscillatory and sector zoning with some instances of xenocrystic cores and rim overgrowths. The primary age modes for RO-10 are 1212 Ma and 1549 Ma. Other significant modes for the sample occur at 1275, 1349, and 1437 Ma. Two minor age modes also occur at 1157 and 1777 Ma (Fig. 4.7A).

## *Neoproterozoic*

### ***RO-8***

The RO-8 sample was collected from the Nova Brasilândia metasedimentary belt. 199 of 315 grains analyzed were 95-105% concordant (Fig. 4.7B). Discordant analyses for RO-8 display normal discordance. Most of the zircons are anhedral to subhedral and very angular to subrounded. RO-8 zircons are typically broken and abraded but still exhibit variable oscillatory zoning. The dominant age mode for this sample is 1572 Ma. Minor modes are also present at 1347 and 1758 Ma. A very small input, 4 zircon grains, is also present in the sample at 1016 Ma. A single grain at 656 Ma is the youngest grain observed in sample RO-8 (Fig. 4.7B).

### ***MT-15***

Detrital zircons from sample MT-15 were collected from sandstone clast within the MT-3 diamictite sample. 315 zircon grains were analyzed from the sample and 261 were between 95-105% concordant (Fig. 4.7C). Discordant analyses fall just below concordia. Zircons from this sample are angular to subrounded and primarily anhedral to subhedral in shape. Oscillatory zoning is present in CL imaging for all the zircons analyzed. The primary mode for MT-15 is 1437 Ma. Three prominent peaks also appear at 1341, 1235, and 1528 Ma and two smaller age modes at 1168 and 1773 Ma (Fig. 4.7C).

### ***MT-3***

Sample MT-3 was collected from the Puga Formation of the late Neoproterozoic Cuiabá group. Zircons from the diamictite are primarily subhedral to euhedral and

angular to subrounded and display very bright oscillatory and sector zoning. Analysis of 315 zircons from the sample produced 296 dates within 95-105% concordance (Fig. 4.8A). There are few discordant analyses for MT-3 and all fall just below concordia. The most prominent age modes in the MT-3 are 1421 and 1345 Ma. Three additional peaks are also represented at 1767, 1522, and 1200 Ma. The two youngest concordant grains in MT-3 both have ages of 1015 Ma (Fig. 4.8A).

### ***RO-12***

RO-12 was collected in central Rondônia from the Pedra Redonda Formation of the Pimenta Bueno graben. 315 zircons were analyzed from RO-12 with 272 concordant analyses (Fig. 4.8B). Analyses that were not concordant show normal discordancy, falling below concordia. Most zircon grains are subhedral to euhedral, very angular to subrounded and show faint to very bright oscillatory zoning and sector zoning. A few of the grains display bright overgrowth rims in CL imaging. The dominant age mode in sample RO-12 is 1547 Ma, and two minor modes are present at 1776 and 1166 Ma. The youngest detrital zircon grain has an age of 624 Ma (Fig. 4.8B).

### ***MT-14***

Sample MT-14 of the Cuiabá Group had 315 grains analyzed and 236 were 95-105% concordant (Fig. 4.8C). Most analyses for MT-14 plot in a linear fashion along concordia but normal discordance is present in a few of the grains. Most of the zircon grains from the sample are subhedral to euhedral and very angular to subrounded. Oscillatory zoning is present in CL imaging for the majority of the zircons and ranges from faint to very bright. MT-14 has several age modes, the most prominent being 1168,

1225, and 1327 Ma. Other notable age modes present in the sample are 1053, 953, 1749, 1561, and 1450 Ma (Fig. 4.8C).

### ***Paleozoic***

#### ***MT-2***

Sample MT-2 from the Cambrian Raizama Formation in southeast Mato Grosso was analyzed, 284 of the 315 grains analyzed were 95-105% concordant (Fig. 4.9 A). A small population of zircon grains show normal discordance off concordia. Most of the grains are subangular to well-rounded and anhedral to subhedral. Zircons typically show oscillatory and sector zoning with some instances of xenocrystic cores and rim overgrowths. Age modes for the sample range from 910-2092 Ma. The most prominent peaks in the sample occur at 1162 and 1305 Ma (Fig. 4.7A).

#### ***MT-1***

MT-1 of the Devonian Furnas Formation had 315 grains analyzed, and 217 were 95-105% concordant (Fig. 4.9 A). Discordant analyses excluded from “best age” modes were normally discordant, falling below the concordia line. Grains from MT-1 were anhedral to euhedral and angular to very well-rounded. Oscillatory and sector zoning are common in CL imaging of the grains, with some instances of xenocrystic cores and rim overgrowths. As with sample MT-2, MT-1 shows multiple age modes present. Age modes range from 539- 2076 Ma, with the most prominent peaks occurring at 539, 620, 1037, and 956 Ma (Fig. 4.8 A).

## CHAPTER V: DISCUSSION

### Introduction

Understanding of the paleogeographic and tectonic relationship between Amazonia and Laurentia can be obtained by observing and interpreting patterns of detrital zircon age spectra from both cratons. In Laurentia it is common practice to interpret detrital zircon age modes by Precambrian crustal age provinces to ascertain the presence or absence of possible sources (e.g., Thomas et al., 2004; Park et al., 2010; Schwartz et al., 2019). In eastern Laurentia these age provinces are typically defined by the Superior (2.5-2.8 Ga), Penokean-Transhudson (1.78-1.9 Ga), Mazatzal-Yavapai (1.65-1.85 Ga), and Granite-Rhyolite provinces (1.3-1.5 Ga); the Grenville orogenic phases (1.37-0.96 Ga); and Appalachian orogenic events (0.47-0.25 Ga) (Whitmeyer and Karlstrom, 2007; Gehrels et al., 2011; Sharman et al., 2015; Chapman and Laskowski, 2019; Schwartz et al., 2019). Detrital zircon studies from North American clastic systems through time repeatedly exhibit age modes that are sourced from sediment derived from Laurentian basement provinces. The recurrence of this pattern allows for provenance distinction among crustal-forming events characteristic of Laurentia.

Assessing the presence and extent of sedimentary recycling, another factor that may lead to misleading or erroneous interpretation of provenance, requires an understanding of the definition of syn- and post-orogenic derived sediment. Synorogenic sediment is defined as being derived from active, ongoing orogenic magmatic and metamorphic events. Sediment characterized as synorogenic is produced during active uplift and deformation in the orogen. Considering timescales of exhumation and erosion during an orogenic cycle, and that zircon is derived primarily from felsic igneous rocks,

syn-orogenic detrital zircon and its associated sediments are likely sourced from volcanic rocks and shallow, rapidly exhumed plutons (Campbell et al., 2005; Reiners et al., 2005). Post-orogenic detrital zircon and sediment is generated after the termination of the active collisional orogenic phase while erosionally-induced uplift and exhumation are ongoing but decaying in rate. In this situation a delay in exhumation results in a lag between the time of crystallization, exhumation and erosion, and transport to the sedimentary basin. Systems with a major component of sediment sourced from older strata in the orogen, an important component of any collisional orogen, usually display detrital zircon age spectra that are dominated by grains from previous orogenic phases and contains little to no evidence of a source that formed during deposition.

An additional fundamental concept to recognize when interpreting detrital zircon analyses is first-cycle derived detrital zircons from crystalline sources and poly-cyclic detrital zircons derived from older sedimentary sources. Zircons derived from first-cycle igneous sources produce relatively simple age distributions that reflect the crystallization age of the source, while poly-cyclic detrital zircons obtained from sedimentary units that have been affected by multiple phases of recycling show more complex patterns from multiple sources (e.g., Link et al., 2005; Gehrels et al., 2011; Schwartz et al., 2019). This results in part because zircon is an ultrastable mineral in sedimentary systems, and along with quartz remains in the sedimentary system effectively forever unless the sedimentary rocks undergo high grade metamorphism. Simply stated, there will be an appearance through time of a greater number of age modes from more sources

Early Mesoproterozoic magmatic events in eastern Laurentia and the midcontinent are represented by the presence of Eastern and Southern Granite Rhyolite

Province basement domains with SHRIMP zircon U-Pb crystallization ages of 1.3-1.5 Ga (Bickford et al., 2015) (Fig. 1.1). The Granite-Rhyolite Provinces were the result of widescale Mesoproterozoic intracratonic extension along a convergent or transform margin that produced numerous A-type plutons across the midcontinent and southwestern United States (Bickford et al., 2015 and references therein).

Similarly, McLelland et al. (2013) and Southworth et al. (2010) found that zircon crystallization ages for magmatic rock comprising the Adirondack terrane and Grenville Appalachian inliers define Grenville magmatic and metamorphic events from the late Mesoproterozoic through the earliest Neoproterozoic (Fig. 1.1). Magmatic events associated with Grenville orogenesis occurred during 5 phases: Pre-Elzevirian: 1.37-1.31 Ga; Elzevirian: 1.26-1.22 Ga; Shawinigan 1.2-1.12 Ga; Ottawan 1.09-1.03 Ga; and Rigolet: 1.01-0.96 Ga. Pre-Elzevirian magmatism at 1.4-1.3 Ga was initiated during rifting of the Laurentian continental margin and the opening of two back-arc basins, producing numerous plutonic bodies exposed in the Adirondacks Highlands Terrane (AHT) and Central Metasedimentary Belt (CMB) (Dickin and McNutt 2007; McLelland et al., 2013). Magmatic zircons from the northern Appalachians, the Mt. Rogers area, the Blue Ridge French Broad massif west of Mars Hill, NC, and the eastern Great Smoky Mountain basement complex yield ages of 1.33-1.37 Ga, coeval with Pre-Elzevirian magmatism identified in the Adirondack terrane (Berquist 2005; Volkert et al., 2010; Tollo et al., 2017; Moecher et al., 2018). The onset of the Elzevirian phase occurred with the closure of the back-arc basins, island arc accretion, and the Elzevirian orogeny (McLelland et al., 2013 and references therein). The Elzevirian phase produced calcalkaline, gabbroic, and granitic plutons in the AHT and surrounding areas

accompanied by widespread metamorphism and tectonic activity (Carr et al., 2000; McLelland et al., 2013). During the early Shawinigan orogeny (~ 1.22 Ga) collisional, subduction tectonic activity was initiated by the closure of the CMB marginal basin and the emplacement of calcalkaline plutons in the Adirondacks Lowlands Terrane (ALT) (McLelland et al., 2013). The main collisional events of the Shawinigan from 1.19-1.14 Ga resulted in deformation and amphibolite-facies metamorphism in both the ALT and AHT. During the waning phases of Shawinigan contractional orogeny, granitoid rocks, anorthosites, and associated gabbros were emplaced within the Grenville Province as a result of delamination of the lithosphere (Emslie et al., 1994; McLelland et al., 2013). The Ottawa phase of the Grenville orogeny at 1.09-1.03 Ga was the result of the final collision between Amazonia and eastern Laurentia. The collision resulted in granulite-facies metamorphism and widespread magmatism (McLelland et al., 2013).

Shawinigan and Ottawa age magmatic rocks have also been identified throughout the Appalachians and the Blue Ridge and are interpreted to represent two pulses of plutonism that was accompanied by widespread regional metamorphism during the Ottawa and early Neoproterozoic. The Rigolet phase (1.01-0.96 Ga) is limited to zircon overgrowth rims in the AHT and is not observed in the ALT (Rivers et al., 2012; McLelland et al., 2013). However, in the northern and southern Appalachians the Rigolet plutonism and high-grade metamorphism is well-represented in areas such as the New Jersey Highlands (Volkert et al., 2010), the Shenandoah massif (Southworth et al., 2010), the Mars Hill terrane (Aleinikoff et al., 2013), and the Pine Mountain uplift (Steltenpohl et al. 2004).

## **The Grenville Signature Through Time**

Age spectra obtained from late Mesoproterozoic and early Neoproterozoic (~1150-1000 Ma) clastic samples from North America show a significant sediment input sourced from the Granite-Rhyolite provinces and older Proterozoic and Archean terranes. Grenville sourced sediment is primarily associated with Shawinigan and Elzevirian orogenic events, with only minor syn-orogenic (Ottawan) sourced sediment present in the samples. By the middle to late Neoproterozoic (~750-540 Ma) Laurentian age spectra show the majority of the sediment contribution coming from Grenville-source terranes. Shawinigan and Ottawan ages dominate the modes, with a small input from earlier Grenville orogenic events. By the early Paleozoic (Cambrian) Laurentian samples continue to be dominated by Shawinigan and Ottawan age modes. However, by this time Ottawan magmatic and metamorphic events become more prevalent in the age spectra and earlier Grenville phases constitute a much smaller proportion of the dated grains. During the middle to late Paleozoic (Ordovician-Permian) Laurentian samples begin to exhibit a much wider array of age modes, yet the major age components continue to be Shawinigan and Ottawan with the appearance of Taconic (~472-440 Ma) sourced sediment coming from Appalachian orogenic events.

In all the Laurentia samples, syn-orogenic sediment is rare to nonexistent, a trend that has been previously observed in Appalachian clastic wedges (Thomas et al., 2004; Becker et al., 2005). The delay in Grenville source sediment within the systems is attributed to a lag in exhumation of Grenville lithologies, as discussed above. After exhumation of Grenville-source components in the Neoproterozoic, clastic sequences become dominated by Grenville sourced sediment as apparent in the late Neoproterozoic

and basal Cambrian samples. By the end of the Paleozoic, Laurentian sedimentary systems display a wider array of age modes suggesting multiple source components, however, Grenville age modes continue to dominate.

$^{40}\text{Ar}/^{39}\text{Ar}$  ages compiled from a ca. 750 km transect in southwestern Brazil for comparison with ages from the Grenville Province in North America show that in Laurentia the Grenville belt exhibits much deeper exhumation, (10-30 km), while in Amazonian depth of exhumation was shallower (5-15 km) ( Tohver et al., 2004, 2006). The volume of rock exhumed calculated from a 1 km wide transect or slice through the crust using the exhumation depth corresponding to the closure temperature for the  $^{40}\text{Ar}/^{39}\text{Ar}$  system in hornblende predicts that more than 8,000 km<sup>3</sup> of material was exhumed and eroded from the North American Grenville belt, whereas in Amazonia only 2,100 km<sup>3</sup> material had been exhumed (Fig. 5.1). The difference in the exhumation volume is attributed to a difference in tectonic regime across Laurentia and into Amazonia. The deeper crustal level exposed in North America is a result of collisional, thrust-dominated stacking of crustal slabs, while the shallow to mid-crustal level exposure in Amazonia marks the suture zone between the two cratons and a change to a strike-slip dominated tectonism that did not involve substantial crustal thickening across most of the orogen (Tohver et al., 2004, 2006).

### **The Grenville Signature in Amazonia**

Samples MT-4, MT-5 and RO-7 represent units sourced entirely from Amazonian tectonic provinces (Fig 5.2 J, K, L). All three samples have generally bimodal age

distributions; MT-4 1524 and 1781 Ma, MT-5 1832 and 2005 Ma, RO-7 1548 and 1776 Ma all corresponding to the Transamazonic (2.25-2.00 Ga) and the Rio Negro-Juruena (1.80–1.55 Ga) tectonic provinces (Santos et al., 2000). Age spectra from samples MT-4, MT-5, and RO-7 lack any evidence for input from outside sediment sources and therefore may be used to define the "Amazonian spectrum" for comparison with younger samples.

Sample MT-13 from the western Aguapeí belt has a depositional age mapped by the Brazilian geologic survey (CPRM) of 1167-1149 Ma. MT-13 has primary age modes at 1310, 1450, 1522, and 1764 Ma. Despite having the same depositional age as the Shawinigan phase of the Grenville, the samples show no evidence for syn-orogenic sedimentation in Amazonia (Fig. 5.2 I). There is Pre-Elzevirian and Elzevirian age modes are present in the sample, but the ages can also be correlated to the Rondônia-San Ignacio (1450–1300 Ma) tectonic province in western Amazonia.

Sample RO-8 from the Nova Brasilândia and shows minor evidence of synorogenic deposition however, most of the sample is comprised of grains coming from the older Rio Negro-Juruena and Rondônia-San Ignacio tectonic events (Fig. 5.2G). It should also be noted that RO-8 also contains 4 concordant grains that correspond to ~1016 Ma, which is younger than the mapped depositional age.

RO-10 was also collected from the Nova Brasilândia metasedimentary belt. Unlike Sample RO-8, which consisted of much older age spectra (1347, 1572, and 1758 Ma), Sample RO-10 shows evidence of synorogenic deposition with dominant age spectra occurring at 1157 and 1212 Ma (Fig. 5.2H).

Samples MT-3, MT-14, and MT-15 of the Cuiabá Group and Puga Formation (ca.630-590 Ma) record a much more complex provenance history. MT-3 and MT-15 of

the Puga diamictite formation exhibit prominent age spectra that correspond to the Shawinigan, Elzevirian, and Pre-Elzevirian phases of Grenville orogenesis but lack evidence of an Ottawa-age component which is commonly recorded in Laurentian samples from the same time interval (Fig. 5.2 C, E and F). Sample MT-14 of the Cuiabá Group shows even more complexity in age modes, attributed to recycling and input from successively younger sources, with dominant peaks at 953, 1053, 1168, 1225, and 1327 Ma (Fig. 5.2C). Although the main spectra in the sample all correlate to Grenville orogenic phases, the Shawinigan and Elzevirian constitute the majority of the age modes present in the sample.

RO-12, of the Pimenta Bueno formation (ca. 622 Ma), shows only minor evidence of syn and post-orogenic sediment deposition, with most of the ages obtained from the sample coming from the Rio Negro-Juruena and Rondônia-San Ignacio tectonic provinces. When comparing RO-12 to samples from the same time interval in Laurentia the amount of syn and post-orogenic sediment in the samples is much smaller, making up only around 5-10% of the overall ages (Fig. 5.2D).

Paleozoic samples, MT-1 and MT-2 show the most input from younger sources with age modes occurring at almost all intervals ((Fig. 5.2 A and B). Cambrian sample MT-2 from the Raizama formation (depositional age 600-542 Ma) exhibits spectra from every phase of Grenville orogenesis, with the most prominent ages coming from grains produced during the Pre-Elzevirian, Shawinigan, and Rigolet phases. MT-1 from the Devonian Furnas formation (ca. 395-360 Ma) displays the most variety in age spectra consistent with recycling from a larger number of sources. MT-1 has dominant age

modes at 956 and 1037 Ma making the Ottawan and Rigolet the primary zircon generating events comprising the sample.

### **Laurentia vs. Amazonia**

Laurentian clastic sequences repeatedly display evidence that Grenville-sourced sediment was abundant and widely available for recycling into successively younger strata. By the late Mesoproterozoic and early Neoproterozoic, Grenville basement begins to supply detritus, as indicated by the appearance of the pre-Elzevirian, Elzevirian, and Shawinigan age modes. By the late Neoproterozoic and basal Cambrian, Grenville-ages dominate zircon age distributions (Fig. 5.2 bottom) consistent with a fully exhumed Grenville orogen. By the end of the Paleozoic age distributions show more complexity associated with multiple phases of recycling from multiple sources, however Grenville ages remain to be the most abundant age modes (Fig. 5.2 bottom).

In Amazonia, a record of Grenville input is much less apparent than in Laurentia. Amazonian samples from the Mesoproterozoic and early Neoproterozoic show little evidence for Grenville-sourced sediment, displaying age modes that are characteristic of Amazonia crustal provinces (Fig. 5.2 top). By the middle to late Neoproterozoic there are only a small number of ages that correlate to Grenville phases. The majority of the ages correspond to early Grenville events of the Pre-Elzevirian and Elzevirian whereas in Laurentia the Grenville doublet, Shawinigan and Ottawan are the dominant phases. It is only by the end of the Neoproterozoic that Grenville sediment begins to comprise a meaningful portion of age distributions from Amazonia samples. By the early and middle Paleozoic, Grenville-sourced grains are more abundant in Amazonian samples, which is

not surprising considering the affect that poly-cycle detrital zircons coming from multiple sources has on age distributions (Schwartz et al., 2019).

Although the continental scale clastic system corresponding to the “Great Grenville Sedimentation Episode”, appears repeatedly in the Laurentian sedimentary record, the same widescale sediment availability and recycling do not appear on the Amazonian side of the orogen. Despite the longevity and hot geothermal conditions that contributed to their abundance in Laurentia, Grenville zircons in Amazonia are rarer until the late Neoproterozoic and Paleozoic. This is most likely due to delayed uplift and sampling from multiple lithologies where Grenville sourced grains were already abundant.

### **Summary and Future Work**

The evidence presented in this study shows that there was not a significant input of Grenville-sourced sediment to Amazonia. Analyses of over 3,000 detrital zircons shows only a small population of grains present, in stark contrast to samples from Laurentia. Despite the amount of evidence presented here, more work could be conducted to better understand the results relationship between Amazonian and Laurentia during Rodinian assembly.

The Sunsas Belt is commonly described as the “Grenville equivalent” orogen in South America. Samples collected from plutons of the Sunsas in central and eastern Bolivia display U-Pb ages of 1075 Ma, coeval with Laurentian Ottawa plutonism (Boger et al., 2005). Similarly, isotopic studies from the Arequipa basement and Antofalla massif in southern Peru have shown them to be exotic and accreted to

Amazonia during Rodinian assembly (Chew et al., 2011). U/Pb geochronology of the Arequipa-Antofalla show that a metamorphic event occurred between 1.20 and 0.94 Ga and is inferred to be related to Grenville orogenic events occurring in Laurentia at the same time (Loewy et al., 2004; Casquet et al., 2008; Reimann et al., 2010; Chew et al., 2011). Although little evidence of Grenville magmatic zircon grains was present in our study, this could be attributed to the distance from the orogenic front where the samples were collected. To understand the true extent of Grenville orogenesis in Amazonia, more samples should be collected from Bolivia and Peru for geochronology and isotopic analyses.

Another constraint that should be applied to the samples would be the addition of analyses from other isotopic systems. Although U/Pb geochronology is ideal for obtaining information on the ultimate magmatic and metamorphic origin of lithologies, other isotopic systems applied to the same samples would complement and refine published results. Lu-Hf, Sm-Nd, and the Pb-Pb systems provide critical information on the chemical differentiation of the Earth and the origin of igneous rocks. Using zircons from previous and newly obtained samples from Amazonia and Laurentia, Lu-Hf and Pb-Pb analyses would help define the magmatic origin of the host zircon bearing lithologies, i.e. juvenile or evolved. Information obtained from analyses of both sides of the orogen could then be used to determine if there was a shared crustal provenance source or mixing between Amazonia and Laurentia and help in reconstructing the paleogeographic relationship between the two cratons during the Proterozoic.

Figure 5.1. Calculated paleodepths for 1.0 Ga from observed cooling rates with 30 °C/km geotherm. Gray line (moving average) is depth of modern surface at 1.0 Ga (10x vertical exaggeration [v.e.]), calculated using  $^{40}\text{Ar}/^{39}\text{Ar}$  thermochronology from hornblende block temperature of 500 °C at 1.1 Ga NBMB—Nova Brasília<sup>ndia</sup> metasedimentary belt; AB—Aguapei<sup>’</sup> belt; PC—Paragua craton; AHL—Adirondack Highlands; FLL—Frontenac-Adirondack Lowlands; CMB—Central Metasedimentary Belt; CGB—Central Gneiss Belt (Adapted from Tohver et al., 2006).

## VITA

Felicia Reneé Harris

### Education:

- Bachelor of Science, Geology, University of West Georgia, Carrollton, Georgia  
2018

### Professional Positions:

- Research Assistant, University of Kentucky, Earth and Environmental Sciences,  
2018-2020
- Teaching Assistant, University of West Georgia, Geology, 2018
- Student Research Assistant, University of West Georgia, Geology, 2017-2018

### Scholastic Honors:

- Outstanding Teaching Assistant, University of Kentucky, Earth and Environmental Sciences, 2020.
- Outstanding Research Scholarship, University West Georgia, Geology, 2018
