ABSTRACT

We present a method for including steady state gas flows in the plasma physics code Cloudy, which was previously restricted to modeling static configurations. The numerical algorithms are described in detail, together with an example application to plane-parallel ionization-bounded H II regions. As well as providing the foundation for future applications to more complex flows, we find the following specific results regarding the effect of advection on ionization fronts in H II regions: (1) Significant direct effects of advection on the global emission properties occur only when the ionization parameter is lower than is typical for H II regions. For higher ionization parameters, advective effects are indirect and largely confined to the immediate vicinity of the ionization front. (2) The overheating of partially ionized gas in the front is not large, even for supersonic (R-type) fronts. For subsonic (D-type) fronts we do not find the temperature spike that has been previously claimed. (3) The most significant morphological signature of advective fronts is an electron density spike that occurs at the ionization front whenever the relative velocity between the ionized gas and the front exceeds about one-half the ionized isothermal sound speed. Observational evidence for such a spike is found in [N II] $\lambda 6584$ images of the Orion bar. (4) Plane-parallel, weak-D fronts are found to show at best a shallow correlation between mean velocity and ionization potential for optical emission lines even when the flow velocity closely approaches the ionized sound speed. Steep gradients in velocity versus ionization, such as those observed in the Orion Nebula, seem to require transonic flows, which are only possible in a diverging geometry when radiation forces are included.

1. INTRODUCTION

The classic early work on the effects of dynamics on the emission structure of H II regions was carried out by Harrington (1977), who studied weak-D fronts in which the gas motions are always subsonic with respect to the front. Within the fully ionized interior of the H II region the gas was found to be close to thermal and ionization equilibrium. Significant nonequilibrium effects induced by the dynamics are confined to the edge of the region, near the ionization front, where there exist large gradients in the radiation field intensity and in the physical conditions of the gas such as temperature and degree of ionization. Harrington found that the dynamics only had a small effect on the integrated forbidden line spectrum of the models he considered. However, there are various reasons to revisit such calculations now.

First, ionization fronts are now studied in a diverse range of astrophysical contexts in which the classical, spherically symmetric, subsonic expansion studied by Harrington may be the exception rather than the rule. Transonic photoevaporation flows seem to be a ubiquitous feature of photoionized regions, rang-

ing in scale from cometary knots in planetary nebulae (López-Martín et al. 2001) and photoevaporated circumstellar disks in H II regions (O’Dell 2001 and references therein) up to champagne flows in giant extragalactic H II regions (Scowen et al. 1998) and the photoevaporation of cosmological minihalos (Shapiro et al. 2004). In such flows, nonequilibrium effects will be somewhat more important than in subsonic weak-D fronts owing to the higher velocities involved. Sankrit & Hester (2000) made a first attempt at detailed modeling of the emission structure of the flow from the head of the columns in M16, using static equilibrium models for the ionization structure.

Second, continuous improvement in the spatial resolution and wavelength coverage of observations, together with advances in theoretical and observational atomic physics, now allows a much more detailed comparison between model predictions and spatially resolved observations of a multitude of emitting species. In this context, even moderate and localized changes in the predicted spectrum due to dynamical effects can be important.

Third, a dynamical treatment allows the self-consistent calculation of the velocity field, which allows comparison with high-resolution spectral line profile observations that provide further constraints on the models. Furthermore, it permits a unified treatment of the entire flow from cold, molecular gas, through the

¹ Work carried out in part while on sabbatical at Department of Physics and Astronomy, University of Leeds, LS2 9JT, UK.

photon-dominated or photodissociation region (PDR), and into the ionized region. Previous studies of nonequilibrium models of PDRs (London 1978; Natta & Hollenbach 1998; Stoerzer & Hollenbach 1998) have tended to treat the PDR in isolation without considering the H II region in any detail. Richling & Yorke (2000) presented numerical radiation hydrodynamic simulations of the photoevaporation of protoplanetary disks, but the physics of the PDR was calculated in a simplified manner.

In common with most other photoionization codes, Cloudy (Ferland et al. 1998; Ferland 2000) has traditionally calculated static equilibrium models in which time-dependent effects are neglected, such as isochoric (constant density) or isobaric (constant pressure) configurations. The task of combining hydrodynamics with detailed simulation of the plasma microphysics can be approached from one of two angles. One method would be to add the atomic physics and radiative transfer processes to an existing time-dependent hydrodynamic code. The other, which is the method pursued in this work, is to add steady state dynamics to an existing plasma physics code.

The current paper is the first in a series of three that will present detailed results from our program to include a self-consistent treatment of steady state advection in a realistic plasma physics code. This first paper introduces the methodology employed in the series as a whole and then concentrates on the restricted problem of “weak” ionization fronts in a plane-parallel geometry. The second paper of the series includes the molecular reaction networks necessary for modeling the neutral/molecular PDR, while the third paper considers “strong D” ionization fronts, where the gas accelerates through a sonic point, as found in divergent geometries such as the photoevaporation of globules.

We first discuss the general problem of advection in ionization fronts (§ 2). We then describe the modifications that have been made to the Cloudy photoionization code in order to treat steady state flow (§ 3). Results from a small sample of representative models are presented in § 4, and the application of our results to observations of the Orion Nebula is discussed in § 5. Further technical details of the physical processes and computational algorithms are presented in a series of appendices.

2. ADVECTION IN IONIZATION FRONTS

The classification of ionization fronts depends on the behavior of the gas velocity in the frame of reference in which the ionization front is fixed (Kahn 1954; Goldsworthy 1961). In this frame, the gas flows from the neutral side of the front (denoted “upstream”) toward the ionized side (denoted “downstream”). If the upstream gas velocity on the far neutral side is subsonic with respect to the front, then the front is said to be *D type*, while if it is supersonic, the front is said to be *R type*. A further distinction is made between those fronts that contain an internal sonic point, which are said to be *strong*, and those that do not, which are said to be *weak*. For example, a weak-R front will have supersonic velocities throughout the front, whereas in a strong-D front the gas starts at subsonic velocities on the neutral side, accelerating through the front to reach a supersonic exhaust velocity on the ionized side. When the downstream gas velocity is exactly sonic, the front is said to be *critical*. There is also the possibility of a *recombination front*, in which the sense of the gas velocity is reversed and the flow is from the ionized side toward the neutral side, with a similar range of possible structures (Newman & Axford 1968; Williams & Dyson 1996). If the gas is magnetized, then the classification becomes more complicated since there are now three wave speeds to take into account (Alfvén speed plus fast and slow magnetosonic speeds) instead of just the sound speed. Thus, one may have a slow-mode

D-critical front, a fast-mode weak-R front, etc. (Redman et al. 1998; Williams et al. 2000; Williams & Dyson 2001).

These classification schemes were developed for plane-parallel fronts but will be approximately valid so long as the radius of curvature of the front greatly exceeds its thickness. This is usually the case since ionization fronts are in general very thin compared with the sizes of H II regions unless the ionization parameter is small (see below). What type of ionization front actually obtains in a given situation depends on the upstream and downstream boundary conditions of the front, in particular the upstream gas density and the downstream gas pressure and ionizing radiation field, together with the large-scale geometry of the flow, which need not be plane parallel.

Since the gas velocity through the front is high for an R-type front, so is the flux of neutral particles that must be ionized for a given upstream density, which in turn requires a high ionizing flux at the downstream boundary. As a result, R-type fronts are usually transient phenomena accompanying temporal increases in the ionizing flux, such as the “turning on” of an ionizing source. In the most common case, the front will be propagating rapidly through slowly moving gas. In the limit of an extreme weak-R front, the gas velocity in the ionization front frame and density are constant throughout the flow.

D-type fronts are more common and the limit of an extreme weak-D front corresponds to a static constant-pressure front in ionization equilibrium. Weak-D fronts require a high downstream pressure and therefore are likely to be found in cases in which the ionization front envelops the ionizing source. Strong-D and D-critical fronts, on the other hand, are consistent with the free escape of the downstream gas and hence apply to divergent photoevaporation flows, for example, from globules.

Advection of material through the ionization front may be expected to have various effects on the emission properties of a nebula. In order to simplify the discussion, we consider a plane-parallel nebula, illuminated at one face by a given radiation field and in a frame of reference in which the ionization front is at rest. This is illustrated in the left panel of Figure 1. The gas is supposed to enter the front from the neutral side with velocity v_n and to leave on the ionized side with velocity v_i . Results from this simplified model are described in § 2.2, but we first discuss the relation between this model and real H II regions.

2.1. Physical Context of Advective Fronts

In this section we consider two typical scenarios in which advective ionization fronts may be encountered and investigate to what extent they may be approximated as steady flows in the frame of reference of the ionization front. In this discussion we follow Shu (1992) in denoting gas velocities in the frame of reference of the ionizing star by u , gas velocities in the frame of reference of the ionization front by v , and pattern speeds of ionization and shock fronts by U .

2.1.1. Classical Strömgren Sphere

The evolution of a classical Strömgren-type H II region in a constant-density medium has been described by many authors (e.g., Goldsworthy 1958; Spitzer 1978; Shu 1992; Dyson & Williams 1997). If the ionizing source turns on instantaneously, then the ionization front is initially R type and propagates supersonically through the surrounding gas with little accompanying gas motion. By the time the ionization front reaches the initial Strömgren radius (where the rate of recombinations in the ionized region approximately balances the ionizing luminosity of the source), the front propagation velocity has slowed to the order of the sound speed in the ionized gas and the front

FIG. 1.—Advective fronts: plane-parallel idealization (*left*); classical Strömgren sphere (*middle*); photoevaporation flow (*right*).

becomes D type, preceded by a shock that accelerates and compresses the neutral gas. The initial R-type phase is very short (of order the recombination timescale) and consequently is of little observational importance. The structure of the region during its subsequent D-type evolution is shown in the middle panel of Figure 1.

The propagation speed of the shock is roughly equal to that of the ionization front and also to the velocity of the gas in the neutral shell,

$$U_s \simeq U_{if} \simeq u_n, \quad (1)$$

whereas the ionized gas expands homologously with a velocity that increases linearly with radius, reaching half the speed of the ionization front at the front itself,

$$u_i = \frac{1}{2} \left(\frac{r}{R_{if}} \right) U_{if}. \quad (2)$$

Hence, the velocity of the ionized gas immediately downstream of the ionization front in the ionization front frame is

$$v_i = u_i(R_{if}) - U_{if} = -0.5U_{if}. \quad (3)$$

The ionization front propagates very slightly faster than the gas in the neutral shell, giving a small upstream neutral gas velocity in the ionization front frame of

$$v_n = u_n - U_{if} < -2c_n^2/c_i \sim 0.1 \text{ km s}^{-1}, \quad (4)$$

where c_n and c_i are the isothermal sound speeds in the neutral and ionized gas, respectively. The evolution of the ionization front propagation speed can be described in terms of its radius as

$$U_{if} = \frac{2c_i}{\left[4(R_{if}/R_{init})^{3/2} - 1 \right]^{1/2}}, \quad (5)$$

where R_{init} is the initial Strömgren radius. The Mach number reached by the ionized gas just inside the ionization front,

measured in the frame of reference in which the front is stationary, is given by $M = 0.5U_{if}/c_i$. This is plotted in Figure 2 as a function of ionization front radius. During the lifetime of a typical O star (and assuming an ambient density of order cm^{-3}), the radius of a classical H II region will expand by roughly a factor of 4, so, as can be seen from Figure 2, $M = 0.3\text{--}0.5$ is typical of the majority of the evolutionary lifetime.

2.1.2. Photoevaporation Flow

Photoevaporation flows are very common in ionized regions, occurring whenever the ionization front is convex from the point of view of the ionizing source, thus allowing the ionized gas to freely stream away from the front. Examples include bright-rimmed globules and proplyds in H II regions and cometary knots in planetary nebulae. On a larger scale, blister-type H II regions can also be considered photoevaporation flows (Bertoldi & Draine 1996).

The right panel of Figure 1 shows the structure of an idealized photoevaporation flow, roughly corresponding to the equilibrium cometary globules of Bertoldi & McKee (1990). The

FIG. 2.—Evolution of the ionization front radius and the “exhaust” Mach number of newly ionized gas in the frame of reference of the advancing ionization front in a classical Strömgren sphere. These quantities are plotted as a function of time since the front reached the initial Strömgren radius, in units of the sound crossing time at that radius.

FIG. 3.—Dynamic slab solutions from the simplified model developed in Appendix A: $\tau_* = 30$, low ionization parameter, fat ionization front (*left panel*); $\tau_* = 3000$, high ionization parameter, thin ionization front (*right panel*). Electron density (solid line) and gas velocity (dashed line) are shown in each case for six models with $\mathcal{M}_m = 0.0, 0.2, 0.5, 0.7, 0.9$, and 0.99 (*right to left*). Electron density is normalized by the fiducial density n_m , velocity is normalized by the maximum sound speed c_m , and distance is normalized by the static Strömgren depth z_0 (see Appendix A for details).

neutral gas is assumed to be approximately at rest with respect to the ionizing source and the ionization front to be D critical with $v_i \simeq u_i \simeq c_i$. The ionization front eats slowly into the neutral gas with $U_i = -v_n = c_n/(2c_i^2) \ll c_i$, and the Mach number reached by the ionized gas at the front will be $\simeq 1$. Outside the front, the ionized gas accelerates as an approximately isothermal wind, as observed around the Orion proplyds (Henney & Arthur 1998).

2.2. Direct and Indirect Effects of Advection

In order to provide some physical insight into advective ionization fronts and to guide the interpretation of the numerical simulations, we have developed a simple analytic model for a plane-parallel weak-D ionization front, in which the gas temperature is assumed to be a prescribed monotonic function of the hydrogen ionization fraction, x . With this assumption, and considering mass and momentum conservation, it is possible to find algebraic solutions for the density, gas velocity, and sound speed as functions of x (see Appendix A). These solutions form a one-parameter family characterized by the maximum Mach number of the gas in the rest frame of the ionization front, reached asymptotically as $x \rightarrow 1$. If we now take into consideration the ionization balance and radiative transfer, one can find a solution for $x(z)$, the ionization fraction as a function of physical depth, by solving a pair of ordinary differential equations.

Apart from the maximum Mach number, $\mathcal{M}_m$, the solutions are found to depend on two dimensionless parameters, ξ_{ad} and τ_* . The first of these, ξ_{ad} (defined in eq. [A18]), is roughly the ratio of recombination length to mean free path of ionizing photons in a D-critical front and is not expected to vary greatly between H II regions, having a typical value of $\xi_{\text{ad}} \simeq 10$. The second parameter, τ_* (defined in eq. [A17]), is roughly the ratio of the thickness of the fully ionized slab to the thickness of the ionization front and is proportional to the ionization parameter at the ionized face: $\tau_* \sim 10^6 \Upsilon$, where $\Upsilon \equiv F_0/(n_0 c)$. The global importance of advection for the system as a whole can be characterized by the parameter λ_{ad} , defined as the ratio of the flux of hydrogen atoms through the ionization front to the flux of ionizing photons at the illuminated face of the slab (eqs. [A10] and [A19]). For small values of λ_{ad} , its value can be approximated as $\lambda_{\text{ad}} \simeq \xi_{\text{ad}} \mathcal{M}_m / \tau_*$. This can be understood as follows: the local effects of advection at the ionization front itself are always substantial (so long as $\mathcal{M}_m$ is not too small), being of order $\xi_{\text{ad}} \mathcal{M}_m$. On the other hand, the partially ionized zone

occupies only a small volume compared with the fully ionized gas unless the ionization parameter is small, so the global effects of advection are reduced by a factor of τ_* .

Detailed results are calculated in Appendix A for both a low ionization parameter model ($\tau_* = 30$) and a high ionization parameter model ($\tau_* = 3000$). The structure of these models for different values of $\mathcal{M}_m$ is shown in Figure 3. In the low- Υ model, the direct global effects of advection are expected to be significant, and indeed the thickness of the ionized slab is reduced by 50% as $\mathcal{M}_m$ approaches unity. In the high- Υ model (more representative of typical H II regions), the direct global effects of advection are expected to be negligible since $\lambda_{\text{ad}} \simeq 3 \times 10^{-3} \mathcal{M}_m$. However, we find that even in this case the thickness of the ionized slab varies by about 5% as $\mathcal{M}_m$ is varied between 0 and 1. This is due to a pronounced peak that develops in the electron density distribution at the ionization front for $\mathcal{M}_m \gtrsim 0.5$ (for a static model the electron density declines monotonically through the front). We also find that the ionization front becomes substantially sharper as $\mathcal{M}_m$ is increased, which is due to a decrease in the ionization fraction for a given value of the optical depth to ionizing radiation. Both these indirect effects of advection have significant effects on the emissivity profiles of optical emission lines (see Fig. 19 of Appendix A), especially those such as [O I] $\lambda 6300$ and [S II] $\lambda \lambda 6716, 6731$ that form close to the ionization front. One can also calculate the spectral profiles of emission lines from the models, as shown in Figures 20 and 21 of Appendix A. Again, it is lines that form in the partially ionized zone that show the most interesting behavior. These may show rms line widths roughly equal to the sound speed and significant velocity offsets, both due to the gas acceleration in the ionization front. The derived widths are roughly 4 times the thermal width of lines emitted by light metals.

Although this analytic model has provided insight into some of the effects of advection, it is obviously deficient in many respects. Many physical processes have been ignored and in particular the use of a fixed temperature profile $T(x)$ does not allow for the fact that $T(x)$ itself may be affected by the advected flow.

3. ADDING DYNAMICS TO CLOUDY

In order to study the structure of advective ionization fronts in greater detail, we need to include a wide range of additional physics. This could be done in a variety of ways, for example, by integrating through the steady state equations or by including

source terms in a time-dependent hydrodynamic simulation. In each case, an implicit treatment of the source terms is necessary, as the many physical processes with timescales shorter than the dynamical timescale lead to the problem being very stiff.

In the present work we have chosen to adapt the photoionization code, Cloudy, which already includes a comprehensive treatment of the physical source terms. Cloudy, in common with other traditional plasma codes, searches for equilibrium solutions of the ionization equations. In order to treat steady advective flows, we have included advective source and sink terms in the equilibrium balance equations. The effect of this is that the equilibrium search phase now in fact determines the implicit solution of the advective equations and so treats short-timescale processes in a stable manner.

In this section we present the basic equations and outline the methods that we use to solve them.

3.1. Equations

Cloudy takes into account the conservation equations for each species and also the heating and cooling balance under the simplifying assumptions of constant density or constant pressure. This procedure can be summarized as balancing source and sink terms for the ionization and energy equations. For the ionization equation in the static case this can be expressed as

$$\frac{dn_i}{dt} = G_i + \sum_{j \neq i} R_{j \rightarrow i} n_j - n_i \left(S_i + \sum_{j \neq i} R_{i \rightarrow j} \right) = 0, \quad (6)$$

where dn_i/dt is the rate of change of the volume density of a particular ionization state, which in equilibrium is equal to zero. The $R_{i \rightarrow j}$ are the rates for ionization (where j is a higher state than i) and recombination (where j is a lower state than i). G_i and S_i cater for processes not included within the ionization ladder and are, respectively, the source of ions from such processes and the sink rate into them. A detailed discussion of the solution method for the ionization networks in the equilibrium case is given in Appendix B.

The general Cloudy solution method works by a series of nested iterations. The innermost loop is the ionization network; external to this is the electron density iteration, which enforces charge neutrality, and then the temperature loop, which enforces thermal balance. Finally, an optional outermost iteration loop varies the density to achieve pressure (or more generally momentum flux) balance. The whole system is iterated until convergence within a given tolerance.

Once dynamics is included, the continuity and momentum equations must be added to the set of equations to be solved, kinetic and internal energy transport and pressure work must be taken into account, and advection terms must be added to the ionization balance equations. For example, for a plane-parallel steady state flow (the simplest case, but one that is applicable to blister H II regions), the equations to solve in flux conservative form are

$$\frac{\partial}{\partial x}(\rho u) = 0, \quad (7)$$

$$\frac{\partial}{\partial x}(p + \rho u^2) = \rho a, \quad (8)$$

$$\frac{\partial}{\partial x} \left[\rho u \left(w + \frac{1}{2} u^2 \right) \right] = H - C, \quad (9)$$

$$\frac{\partial}{\partial x}(n_i u) = G_i + \sum_{j \neq i} R_{j \rightarrow i} n_j - n_i \left(S_i + \sum_{j \neq i} R_{i \rightarrow j} \right). \quad (10)$$

Here a is an acceleration, e.g., gravity or radiation driving; w is the specific enthalpy $w = \varepsilon + p/\rho$, where ε is the specific internal energy; and $H - C$ is heating minus cooling. Here the specific internal energy includes only the thermal energy of translation, so $\varepsilon = \frac{3}{2}(p/\rho)$, as transfers from other physical energy components (ionization energy, binding energy, vibration and rotation energy of molecules, etc.) are treated as explicit heating and cooling terms in the underlying thermal balance scheme.

The advection terms have the general form of $\nabla \cdot (n_i \mathbf{v})$ (for steady state), where $\mathbf{v}$ is the advection velocity. This can be written as

$$\nabla \cdot (n_i \mathbf{v}) = n \mathbf{v} \cdot \nabla (n_i/n). \quad (11)$$

3.2. Differencing Scheme

Although it is possible to solve the ionization equations in an explicitly time-dependent way, this is not the best way to proceed. The photoionization terms in the steady state solution will often have very short timescales, so stability constraints would limit the time step to this short photoionization timescale and hence cause an extremely slow convergence of the iterative scheme. Instead, we take advantage of the current algorithm used by Cloudy and difference the equations implicitly. Such an implicit scheme has the advantage that the time step is not limited to the shortest ionization or recombination time, which is clearly unsatisfactory for an astrophysical system in which the dynamical timescales are general much longer than the ionization or recombination timescales.

At iteration m , the advection terms may be approximated based on the value in the present zone and an upstream value in the previous full iteration as

$$\frac{d}{dz} x_i \rightarrow \frac{x_i^m(z) - x_i^{m-1}(z - \Delta z)}{\Delta z}, \quad (12)$$

where $x_i^m(z)$ is the value of $x_i = n_i/n$ at position z at the m th iteration of the scheme and Δz is an adjustable *advection length*. For the first iteration no upstream values are available so no advection terms are included in the equations. It is useful to define the look-back operator

$$L_{\Delta z}[x_i^m(z)] = x_i^{m-1}(z - \Delta z) \quad (13)$$

for values, such as x_i , given per unit material. Values specified per unit volume need to be scaled to a conserved variable before the look-back is applied, so that

$$L_{\Delta z}[n_i^m(x)] = n^m x_i^{m-1}(z - \Delta z). \quad (14)$$

This may be thought of as a first-order Lagrange remap solution for the advection equation.

For the scheme discussed in Appendix B for the ionization ladder, the advective terms may then be included simply as an additional source term,

$$G_i = n \mathbf{v} \cdot \frac{L_{\Delta z}[x_i^m(z)]}{\Delta z}, \quad (15)$$

and sink rate,

$$S_i = \frac{v}{\Delta z}, \quad (16)$$

FIG. 4.—Convergence behavior of an example model as a function of iteration number, m . Solid line: advection length Δz (units of 10^{15} cm); dashed line: convergence error, ϵ_1 ; dotted line: discretization error, ϵ_2 .

in the linearized form of the equations, and iterated to find the nonlinear solution as in the time-steady case.

The energy balance equation may be treated in a similar manner. Using the mass conservation equation (eq. [7]), we have from equation (9)

$$\rho \mathbf{v} \cdot \nabla \left(w + \frac{1}{2} v^2 \right) = H - C, \quad (17)$$

which may be differenced as

$$\rho v \frac{[w + (1/2)v^2] - L_{\Delta z}[w + (1/2)v^2]}{\Delta z} = H - C. \quad (18)$$

The terms on the left-hand side of this equation may then be treated as additional heating and cooling terms in the temperature solver.

The continuity and momentum equations are more easily dealt with. The continuity equation is taken into consideration simply by eliminating the velocity v in terms of ρ in all equations using the substitution

$$\rho v r^d = \text{const}, \quad (19)$$

which comes from integrating the general form of equation (7) where $d = 0, 1$, or 2 indicates plane-parallel, cylindrical, or spherical geometry, respectively. The initial condition is given at the illuminated face.

The dynamical pressure, which appears in the momentum equation, is taken into account by adding the ram pressure term ρv^2 to the total pressure.

3.2.1. Varying the Advection Length

The advection length, Δz , in this scheme determines the manner in which different processes are treated. The differencing we have chosen has the effect that processes far more rapid than $\Delta z/v$ are treated as in static equilibrium, while slower processes are followed exactly. The correct steady state solution is found in the limit $\Delta z \rightarrow 0$, but the smaller the advection length chosen, the longer the system will take to reach an equilibrium state. The natural procedure is then to use a first iteration solution by ignoring the advection terms and then gradually decrease Δz until $\Delta z \sim \Delta z_{\text{grid}}$, where Δz_{grid} is the size of a spatial zone in the simulation, at which stage the treatment of advection will be as accurate as that of photoionization.

In order to track the convergence of the models and to determine when to reduce the advective time step, we monitor the

behavior of two error norms, ϵ_1 and ϵ_2 . Both are calculated as the squared norm over all zones, z , and ionic/molecular species, i . The first of these norms is the *convergence error*, defined as

$$\epsilon_1 = \left\| \frac{n_i^m - n_i^{m-1}}{\Delta z/v} \right\|_{z,i}, \quad (20)$$

which measures the difference between the model solutions for the last two iterations. The second is the *discretization error*, defined as

$$\epsilon_2 = \left\| \frac{n_i - L_{\Delta z}(n_i)}{\Delta z/v} - \frac{n_i - L_{(\Delta z/2)}(n_i)}{\Delta z/2v} \right\|_{z,i}, \quad (21)$$

which measures the accuracy of the present estimate of the advective gradients in the solution compared to an estimate with half the advection length.

If $\epsilon_1 \ll \epsilon_2$, then the solution is converged with the present Δz , while if the errors in the Lagrangian estimate of the gradient of the value are still significant, then the time step should be decreased. Cutting Δz when $\epsilon_1^2 < 0.1\epsilon_2^2$ produces substantial improvements in the rate of convergence of the advective solutions. However, it can still take a substantial number of iterations to reach equilibrium for large advection velocities.

An example of the way in which Δz , ϵ_1 , and ϵ_2 vary during a model calculation is given in Figure 4 (which corresponds to model ZL009 discussed in the following section). It can be seen that while Δz_{ad} remains constant, the convergence error, ϵ_1 , decreases with each iteration, while ϵ_2 hardly changes after the first iteration for a given Δz . When ϵ_1/ϵ_2 falls to a low enough value, then all physical processes that occur on timescales longer than $\Delta t = \Delta z/v$ have converged, so the advection length can be reduced. This has the effect of lowering ϵ_2 but also temporarily increases ϵ_1 as a result of the release of shorter timescale processes from strict local equilibrium, so several iterations must be carried out at the new value of Δz . This procedure is continued until ϵ_2 has fallen to a sufficiently low value.

4. RESULTS

In this section we present results for selected advective ionization fronts calculated using Cloudy, all using a plane-parallel slab geometry. The principal input parameters for the models are the hydrogen number density, n_0 , gas velocity, u_0 , and hydrogen-ionizing photon flux, F_0 , all specified at the illuminated face. The spectral distribution of the incident radiation field was assumed to be a blackbody with effective temperature, T_{eff} . All these parameters are shown in Table 1 for the three models presented here. The gas-phase elemental

TABLE 1
MODEL PARAMETERS

Parameter	ZL009	ZH007	ZH050
$\log(n_0/\text{cm}^{-3})$	3.5	4.0	4.0
u_0 (km s $^{-1}$)	−9.0	−7.0	−50.0
$\log(F_0/\text{cm}^{-2})$	9.5	13.0	13.0
$\log(T_{\text{eff}}/\text{K})$	4.6	5.0	4.6
$\log(B_0/\text{G})$	...	−4.0	−4.0
$\log Y_0$	−4.5	−1.5	−1.5
τ_*	9.9	6800	6800
$\mathcal{M}_m$	0.84	0.73	4.01
ξ_{ad}	8.1	13.8	13.8
λ_{ad}	2.2	0.0015	0.008

FIG. 5.—Structure of model ZL009 as a function of depth from the illuminated face. (a) Velocity and isothermal sound speed. (b) Gas temperature. (c) Number density of hydrogen nucleons. (d) Hydrogen ionization fraction. (e) Helium ionization fractions. Panels (b)–(e) show the advective model results (solid line) and the results from an equivalent static constant-pressure model (dashed line).

abundances for all the models were set at the standard interstellar medium values (Baldwin et al. 1996), and Orion-type silicate and graphite grains were included (Baldwin et al. 1991). Since this paper is concerned with the effects of advection on the ionization front, all molecules were turned off and the integration was stopped when the electron fraction fell below 10^{-3} . The inclusion of molecular processes in the PDR will be described in a following paper. The models also include an approximate treatment of a tangled magnetic field (see Appendix C), characterized by the field strength at the illuminated face, B_0 .

One further physical process was disabled in these models: the radiative force due to the absorption of stellar continuum radiation (principally by dust grains). This was done for purely pragmatic reasons, since the inclusion of this process for high ionization parameter models makes it very difficult to set the approximate desired conditions at the ionization front by varying conditions at the illuminated face. Models that do include this process are discussed further in § 5.2.

The first two models, ZL009 and ZH007, are weak-D fronts with low and high ionization parameter, respectively, with parameters similar to the toy models discussed in Appendix A. The velocity at the ionized face, u_0 , was set somewhat below the isothermal sound speed in order to avoid the possibility of gas passing through a sonic point during an intermediate iteration (transonic fronts will be considered in a following paper). The third model, ZH050, is a weak-R front in which the gas velocity relative to the front is supersonic throughout. Such R-type

FIG. 6.—Emissivity structure of model ZL009. Same as Fig. 5, but showing volume emissivity of (a) $H\alpha$ $\lambda 6563$, (b) $[N\ II]$ $\lambda 6584$, (c) $[O\ I]$ $\lambda 6300$, (d) $[S\ II]$ $\lambda\lambda 6716, 6731$, and (e) $[O\ III]$ $\lambda 5007$.

fronts are likely to be transient and thus of limited observational significance. Nevertheless, this model is useful since it provides a stringent test of our simulations in the limit of high advective velocities.

As well as the advective models, we also calculate equivalent static models for each of the three cases considered, which have constant pressure for comparison with the weak-D fronts or constant density for comparison with the weak-R front.

4.1. Low-Ionization Parameter, Weak D

This model, ZL009, has physical parameters that are inspired by those of cometary globules in planetary nebulae such as the Helix, although the geometry is plane parallel rather than spherically divergent. The ionization parameter of the model is very low ($\Upsilon = 3.33 \times 10^{-5}$), which accentuates the global effects of advection and also leads to the ionization front thickness being comparable to the Strömgren thickness of the ionized layer.

As can be seen from Figures 5 and 6, the advection has large effects on the model structure as would be expected given the large value of λ_{ad} . The depth of the ionized region is reduced by more than a factor of 2 with respect to the static model, with concomitant reductions in the brightness of the hydrogen recombination lines (see Table 2). The collisional lines of $[O\ I]$, $[S\ II]$, and $[N\ II]$ are also reduced in intensity, albeit to a lesser degree ($[O\ III]$ emission from this model is negligible owing to the low ionization parameter). Interestingly, the intrinsic Balmer decrement is increased in the advective model, which gives $H\alpha/H\beta = 3.29$ (reddening by internal dust is not included in the line ratios given in Table 2). This is because the temperature at

TABLE 2
EMISSION-LINE PROPERTIES FROM WEAK-D PHOTOIONIZATION MODELS

LINE	MODEL ZL009				MODEL ZH007			
	LINE INTENSITY		$\bar{v}$	Δv	LINE INTENSITY		$\bar{v}$	Δv
	Static	Advect			Static	Advect		
H α λ 6563	2.95	3.29	-5.89	21.6	2.92	2.92	-6.46	20.0

[O III] λ 5007	0.05	0.03	-7.50	6.1	5.21	5.21	-6.32	5.0
H β λ 4861	-2.868	-3.382	...	...	0.435	0.440	...	...

NOTE.—Line intensities are all calculated for a face-on orientation and are given relative to H β except for H β itself, which is $\log(\text{intensity})$ in units of $\text{ergs cm}^{-2} \text{s}^{-1}$.

low-ionization fractions is significantly higher in the advective model, which leads to a nonnegligible collisional contribution to the Balmer emission that preferentially excites H α . The temperature in the more highly ionized zone is also increased somewhat by the effects of advection.

Also listed in Table 2 are the mean velocities and FWHM of the different emission lines, calculated assuming that the model is observed face-on. The emission-line profiles are illustrated in Figure 7. The contribution from each computational zone to the line profile is thermally broadened using the local temperature and the atomic weight of the emitting species. As a result, the H α line is significantly broader than the collisionally excited metal lines. The [N II] line is blueshifted with respect to [S II] and [O I], which is due to the acceleration of gas through the ionization front, as can be seen in Figure 5a. The H α line has two components: a broad blueshifted component due to emission from the ionized flow, and a narrow component at zero velocity, caused by a subsidiary peak in the electron density that occurs at low-ionization fractions where the temperature changes sharply.

For the [S II] line, the thermal broadening and the gas acceleration both contribute in equal amounts to the predicted line width. For the lighter metal lines, the acceleration broadening remains roughly the same but the thermal width is increased somewhat. For H α , the thermal broadening dominates.

In this model, the gas velocity and Mach number increase monotonically as the gas flows from the neutral to the ionized

side, reaching a maximum Mach number of $\mathcal{M}_m = 0.84$ at the illuminated face. As a result, emission lines from more highly ionized species are more blueshifted (see Table 2). However, the effect is slight with only 2.5 km s^{-1} velocity difference between [O I] and [O III].

4.2. High Ionization Parameter, Weak D

This model, ZH007, has physical parameters (see Table 1) inspired by the central region of the Orion Nebula (Baldwin et al. 1991). The density is only slightly higher than in ZL009, but the ionizing flux is much higher, resulting in a far higher ionization parameter ($\Upsilon = 3.3 \times 10^{-2}$). The ionization front is much thinner than the depth of the fully ionized slab. The local advection parameter, ξ_{ad} (see § 2 and Appendix A), is somewhat higher than in the previous model as a result of the hotter gas temperature and softer ionizing spectrum, but the much higher value of τ_* that accompanies the higher ionization parameter means that the global advection parameter, λ_{ad} , is very small.

The structure of the advective model as a function of depth into the slab from the illuminated face is shown by solid lines in Figure 8. For some panels, an equivalent constant-pressure, static model is also shown (*dashed lines*). The indirect effects of advection are much greater than the direct loss of 0.1% of the incident ionizing flux due to the ionization of fresh gas. The largest effect is a roughly 3% increase in the mean density in the ionized zone (the densities at the illuminated faces are set equal in the static and advective models) due to the varying importance of ram pressure as the velocity varies through the slab. Because of the difference in density dependence of recombination and dust absorption, this leads to a slight decrease in the ionized column density together with an increase in the emission measure, caused by a reduction in the fraction of ionizing photons that are absorbed by dust grains.

Figure 9 shows some of the same quantities as in Figure 8, but this time plotted against the electron fraction, $x_e = n_e/n$. This effectively “zooms in” on the ionization front transition itself, allowing one to appreciate details of the structure that are not apparent in the plots against depth. Note that the more neutral gas is on the left in Figure 9, whereas it was on the right in Figure 8. In Figure 9b, which shows the temperature profiles, it can be seen that the initial heating of the gas as it is ionized is more gradual in the advective model than in the static model as a result of the photoheating timescale being longer than the dynamic timescale. However, once the ionization fraction exceeds about 20%, the photoheating rate exceeds the static equilibrium model because the neutral fraction at a given value of the ionizing flux is higher than in the static case. This produces

FIG. 7.—Face-on emission line profiles of model ZL009 including thermal broadening: H α λ 6563 (thick solid line), [N II] λ 6584 (thin solid line), [O I] λ 6300 (thick dashed line), [S II] λ 6731 (thin dashed line), and [O III] λ 5007 (dotted line). All lines are normalized to their peak intensities.

a characteristic overheating, which is often seen in advective fronts. In the current case it is relatively modest, producing an extended 10^4 K plateau for $x_e = 0.3$ – 0.9 . For $x_e > 0.9$ the gas approaches static thermal equilibrium again and the two curves coincide with temperature variations determined by radiation hardening and the varying importance of the diffuse field. Figure 9c shows the variation in the gas density, and it can be seen that the density on the far neutral side is significantly higher in the advective model. This is a result of the lack of ram pressure on the neutral side (see Fig. 9e), which means that the thermal pressure must increase to compensate. The magnetic field at the illuminated face in this model was set to be 0.1 mG, implying a negligible contribution to the total pressure in the ionized gas. However, on the far neutral side, where the density is higher, the field is much larger (assumed to grow with compression as $B \propto \rho^{2/3}$; see Appendix C), so that the magnetic pressure becomes appreciable, limiting the density in the cold gas. The inferred B in the neutral gas is similar to observed values in the neutral veil of Orion (Troland et al. 1989).

The line emissivities as a function of depth for the ZH007 model are shown in Figure 10. The main change between the static and advective models is the sharp peak at the ionization front that is seen in the emissivity of lines from singly ionized species such as [N II]. This peak is due to the electron density peak seen in Figure 3 and discussed in Appendix A.

The integrated emergent emission line spectrum (Table 2) is barely affected by the advection. As a result of the increase in emission measure discussed above, although the ionization front moves appreciably inward (Fig. 8d), the Balmer line flux is actually slightly *higher* in the advective model than in the static model. On the other hand, lines that form in the ionization

FIG. 9.—Structure of model ZH007 as a function of electron fraction, n_e/n . Panels (a)–(c) as in Fig. 8. (e) Partial contributions to the total pressure: thermal gas pressure (medium weight line), magnetic pressure (thin line), and ram pressure (thick line).

front itself, such as [S II] and [O I], are somewhat reduced in intensity in the advective model as a result of the narrowing of the ionization front by advection (see discussion in Appendix A).

Unlike in the low ionization parameter model of the previous section, in this model the velocity and Mach number do not increase monotonically from the neutral to the ionized side. Instead, the maximum Mach number ($\mathcal{M}_m = 0.73$), which also corresponds to the maximum velocity, occurs at the He^0/He^+ front. Although this does not correspond to the maximum temperature, it is a maximum in the sound speed owing to the decrease in the mean mass per particle when He is ionized. There is a second, slightly lower, maximum in the sound speed, Mach number, and velocity just inside the H ionization front where radiation hardening causes a temperature maximum. The velocity also starts to increase again very close to the illuminated face.

Because of this complex velocity structure, the trends of blueshift with ionization parameter are less clear in this model, as can be seen from Table 2 and from Figure 11, which shows simulated emission-line profiles.

4.3. High Ionization Parameter, Weak R

This model, ZH050, is identical to ZH007 except that the gas velocity at the illuminated face is set to 50 km s^{-1} , producing a weak-R front. The model structure as a function of depth is shown in Figure 12 and as a function of electron fraction in Figure 13. In both cases, the advective model is now compared with a constant-density static model as opposed to the constant-pressure model that was used for comparison with the weak-D models. As can be seen from Figures 12a and 12c, the velocity

FIG. 10.—Emissivity structure of model ZH007 in units of 2×10^{-16} ergs $\text{cm}^{-3} \text{s}^{-1}$. Panels as in Fig. 6.

and density are roughly constant across the front, as is expected in the weak-R case. The extremal Mach number in the front (which for R-type fronts is a minimum; see Appendix A) is $\mathcal{M}_m = 4.01$, which occurs on the ionized side of the front (see Fig. 13c) at $x_e \simeq 0.93$.

4.4. Temperature Structure of the Ionization Fronts

Figure 12b shows that our weak-R model has a pronounced temperature spike at the ionization front, together with a smaller spike at the He ionization front. Figure 13b shows that this is a more extreme manifestation of the overheating in the ionization front that was seen in the weak-D model (Fig. 9b). However,

FIG. 11.—Face-on emission line profiles of model ZH007 including thermal broadening: H α $\lambda 6563$ Å (thick solid line), [N II] $\lambda 6584$ Å (thin solid line), [O I] $\lambda 6300$ Å (thick dashed line), [S II] $\lambda 6731$ Å (thin dashed line), and [O III] $\lambda 5007$ Å (dotted line). Vertical axis units are arbitrary.

even in this case of a rapidly propagating front we do not find the overheating to be very great, reaching a maximum temperature of only 13,000 K. Other authors have found more pronounced overheating effects in dynamic ionization fronts (Rodríguez-Gaspar & Tenorio-Tagle 1998; Marten & Szczerba 1997) but for different values of the physical parameters. Marten & Szczerba (1997) found temperatures as high as 20,000 K behind R-type fronts moving at a substantial fraction of the speed of light, which would be difficult to model using our steady state code. Rodríguez-Gaspar & Tenorio-Tagle (1998) studied the time-dependent evolution of an H II region after the turning on of an O star, finding temperatures of order 15,000 K behind the ionization front soon after its transition from R to D type. Their higher temperatures may be due to these authors including fewer cooling processes than are included in Cloudy (for further discussion see Williams & Dyson 2001 and references therein). The greater width of the temperature spike in the Rodríguez-Gaspar & Tenorio-Tagle (1998) models is due to the fact that they were considering lower densities, so the gas moves farther from the ionization front in the time it takes to cool to the equilibrium temperature.

5. DISCUSSION

In this section we look for evidence of advective effects in one of the closest and best-studied H II regions, the Orion Nebula. We concentrate on the clearest signatures of advection to emerge from our simulations: the electron density spike and the ionization-resolved kinematics.

5.1. Electron Density Structure of the Orion Bar

One firm prediction of the advective model that differs from the static case is the existence of a sharp electron density peak at the position of the ionization front. This peak manifests

itself most clearly in the emission of the $[\text{N II}]$ $\lambda 6584$ line (see Fig. 10), producing a narrow emissivity peak at the edge of the broader peak that comes from the neutral helium zone. In Figure 14 we show an $[\text{N II}]$ image of the bright bar region in the Orion Nebula that shows evidence of just such a structure.² The bar is believed to be a section of the principal ionization front in Orion that is seen almost edge-on. It can be seen as a diffuse strip of $[\text{N II}]$ emission (width $\simeq 10'' \simeq 6 \times 10^{16}$ cm) stretching from the top left to bottom right of the image. The principal source of ionizing radiation is the O7 V star θ^1 Ori C, located off the image to the northwest. A sharp, bright edge to the emission can be seen on its southeast side along a considerable fraction of the bar, which may correspond to the electron density peak.

The geometry of the nebula in the vicinity of the bar is far more complicated than the plane-parallel geometry assumed in the models, making a quantitative comparison difficult. The bar probably consists of at least two overlapping folds in the ionization front, and its appearance is also affected by protruding fingers of neutral gas and interactions with the HH 203/204 and HH 528 jets. However, the straight region of the bar to the northeast of the HH 203/204 bow shocks shows a relatively simple structure, which we attempt to compare with our model predictions. We present in Figure 15 emission-line spatial intensity profiles along a short section of narrow slit parallel to the bar, with position as indicated in Figure 14. Comparison of Figure 15 with the model profiles of Figure 10 shows good general agreement.

The electron density in the bar region has been measured from the $[\text{S II}]$ $\lambda 6716/\lambda 6731$ line ratio to be around 4000 cm^{-3} (Wen &

² This image is based on data obtained with the WFPC2 instrument on the *Hubble Space Telescope*, provided by C. R. O'Dell.

FIG. 15.—*HST* WFPC2 spatial intensity profiles of various emission lines along a line perpendicular to the Orion bright bar. The ionizing source lies off the graph at an offset of $\simeq -120''$.

O'Dell 1995; García Díaz & Henney 2003), whereas model ZH007 predicts a value of $\simeq 8000 \text{ cm}^{-3}$ for the [S II]–derived density. On the other hand, the incident ionizing flux can be estimated to be about $5 \times 10^{12} \text{ cm}^{-2}$, which is half that of the model ZH007. Thus, the model has the same ionization parameter as the bar and the results can be directly compared by multiplying the model lengths by a factor of 2 such that the spatially broad component to the [N II] emission is predicted to have a thickness of $\simeq 4 \times 10^{16} \text{ cm} \simeq 7''$, in reasonable agreement with what is observed. The electron density peak at the ionization front is predicted to have a thickness of $\simeq 2 \times 10^{15} \text{ cm} \simeq 0.3''$, which is also very close to the observed thickness of the narrow ridge in [N II] (note that this thickness is fully resolved by the *Hubble Space Telescope* [*HST*], which has an angular resolution of $\simeq 0.1''$ at optical wavelengths).

5.2. Velocity-Ionization Correlation in the Orion Nebula

The mean velocity of different optical emission lines from the core of the Orion Nebula has long been known to correlate with the ionization potential of the parent ion (Kaler 1967; O'Dell et al. 1993, 2001; Henney & O'Dell 1999; Doi et al. 2004). Lines from more highly ionized species such as [O III] $\lambda 5007$ are blueshifted by approximately 10 km s^{-1} with respect to the molecular gas of OMC-1, which lies behind the nebula, with intermediate-ionization species such as [N II] $\lambda 6584$ being found at intermediate velocities.

The results of § 4 show that just such a correlation can be qualitatively reproduced by our models. However, on closer inspection, many significant differences are revealed between the model results and the Orion observations. A much clearer velocity-ionization correlation exists in model ZL009 (low ionization parameter) than in ZH007 (high ionization parameter, more pertinent to the Orion Nebula), as can be seen from Table 2 and Figures 7 and 11. This is not surprising since the emission in the high ionization parameter model is dominated by ionized equilibrium gas, where velocity changes are rather small and are driven by variations in the thermal balance (the complex interplay of radiation hardening and the excitation of different coolant lines) rather than being directly caused by ionization changes. Furthermore, both the magnitude of the velocity shifts seen in the models and the broadening induced by the gas acceleration are somewhat smaller than is observed in Orion.

In order to better reproduce the observations, what is required is a means of continuing the acceleration of the gas inside the body of the nebula, where hydrogen is fully ionized. There are

FIG. 16.—Structure of model ZHR012, which includes the continuum radiation force. (a) Velocity and isothermal sound speed. (b) Partial contributions to the total pressure: thermal gas pressure (medium weight line), ram pressure (thin line), integrated radiative force (thick line), resonance line radiation pressure (dashed line), and magnetic pressure (dotted line).

two means by which this might be achieved: (1) by including the continuum radiation force on the ionized gas/dust mixture, or (2) by considering a transonic strong-D ionization front in a nonplane, divergent geometry.

The results of a model that includes the continuum radiation force are shown in Figure 16. The thick line in Figure 16b shows the integral along the radiation propagation direction of the radiative force per unit volume, f_{rad} , that acts on the material in the flow.³ In response to this radiative forcing, the total pressure increases with depth and, since the flow is subsonic, the gas pressure and density increase in the same direction. By mass conservation, this leads to an acceleration of the gas toward the illuminated face, as can be seen in Figure 16a (compare Fig. 8a, where this process is absent).

However, this acceleration of the fully ionized gas does not have a very large effect on the mean velocity of the emission lines, as can be seen from Figure 17. This is because the higher velocity gas represents only a small fraction of the total emission, even for the [O III] line. Although the model ZHR012 does show a clear relation between velocity and ionization (unlike ZH007), the gradient is very small, being less than 1 km s^{-1} between [O I] and [O III], compared with an observed difference of $5\text{--}10 \text{ km s}^{-1}$ in the Orion Nebula. In addition, any deviations

³ The dust-gas drift velocity is always much slower than the flow velocity in these models, so it is valid to suppose that the gasdynamics and dust dynamics are perfectly coupled.

FIG. 17.—Mean velocities of common optical emission lines from plane-parallel advective models in face-on orientation. The ionization potential of the parent ion increases from left to right.

from a strictly face-on orientation of the observer would tend to reduce the observed gradients.

In order to reproduce the observed kinematics of the Orion Nebula, one needs a strong acceleration of the gas in the region between the hydrogen and helium ionization fronts, since this is the region where the ionization of heavy elements such as oxygen and sulfur is changing most swiftly. We have shown that it is not possible to achieve this with a plane-parallel model. In such a geometry, gas acceleration requires either a gradient in the sound speed or the application of a body force, neither of which are present with the required magnitude in the relevant region. Strong changes in the sound speed only occur at greater depths, in the hydrogen ionization front, while the effective gravity associated with continuum radiation pressure acts mainly at shallower depths, where the heavy-element ionization is not changing.

On the other hand, as we will show in a following paper, the requisite acceleration is a natural consequence of models in which the flow is divergent (either spherical or cylindrical) rather than plane parallel. Although such models are obviously relevant to such objects as proplyds (Henney & O'Dell 1999) and photoevaporating globules (Bertoldi & McKee 1990), it is not so apparent that they should apply to the large-scale emission from the Orion Nebula, which has been traditionally visualized as a bowl-like cavity on the near side of the molecular cloud OMC-1. However, three-dimensional reconstruction of the shape of the ionization front (Wen & O'Dell 1995) indicates that the radius of curvature of the front is larger than its distance from the ionizing star. In such a case, the divergence of the radiation field can lead to a (weaker) divergence of the flow (Henney 2003). Another possibility is that the mean flow is the superposition of multiple divergent flows from the many barlike features that have been found in the nebula (O'Dell & Yusef-Zadeh 2000).

6. CONCLUSIONS

In this paper we have developed a method for including the effects of steady material flows in the plasma physics code Cloudy (Ferland 2000), which was previously capable of modeling only static configurations. We have presented a detailed description of the numerical algorithms and an example application to the restricted problem of plane-parallel ionization-bounded H II regions where the flow does not pass through a sonic point (weak fronts). The most important conclusions from our study are as follows:

1. The local effects of advection are most important in those regions of the flow where physical conditions are strongly varying over short distances, such as in the hydrogen ionization front.
2. The global effects of advection on an H II region depend on the relative thicknesses of the ionization front and the region as a whole, which is a function of the ionization parameter. Only for low values of the ionization parameter, such as are found in cometary knots of planetary nebulae, do we find a significant direct effect of advection on the emission properties integrated over the entire region. For higher ionization parameters, more typical of H II regions around O stars, the effects of advection are indirect and more localized.
3. One such indirect effect is a modification of the temperature structure in the ionization front due to the overheating of partially ionized gas. However, we find the magnitude of this effect to be much less than has previously been claimed (Osterbrock 1989; Rodriguez-Gaspar & Tenorio-Tagle 1998), probably as a result of our more realistic treatment of heating and cooling processes. For weak D-type fronts (subsonic flows), the temperature reached in the front does not exceed the equilibrium

temperature in the fully ionized gas (see Fig. 9b). Even for supersonic R-type fronts, the peak temperature is only about 20% higher than the equilibrium ionized value (see Fig. 13b). The temperature increase causes an increase in the peak emissivity of the [O I] $\lambda 6300$ line, but the total emission of this line tends to be less than in an equivalent static model because advection acts to sharpen the ionization front and hence decreases the width of the zone where [O I] is emitted.

4. Another indirect effect of advection in high ionization parameter regions is the production of a sharp spike in the electron density, which occurs at the ionization front whenever the peak Mach number in the flow exceeds about 0.5. This spike does not occur in static models, and its existence can be shown analytically to be a consequence of the exchange between thermal pressure and ram pressure as the gas is accelerated through the front (Appendix A, Fig. 18). As such, it can serve as a useful diagnostic for the presence of advection in ionization fronts, best observed in the [N II] $\lambda 6584$ line, for which advective models predict a two-component structure (Fig. 10b): a broad peak of emission from the equilibrium H⁺-He⁰ zone plus a narrower peak from the n_e spike at the ionization front. Just such a structure is seen in *HST* images of the Orion bar (§ 5.1), suggesting that advection is important in that region.

5. Finally, the advective models provide a mapping between the ionization state of the gas and its velocity and can hence be used to predict kinematic profiles of different emission lines, which can be compared with spectroscopic observations. We make such a comparison in the case of the Orion Nebula but find that the plane-parallel models presented in this paper are utterly incapable of explaining the observed kinematics (§ 5.2). The observations seem to demand a strong acceleration of the gas in the region between the hydrogen and helium ionization fronts, whereas the only acceleration mechanisms that can act in the plane-parallel models occur at either greater depths (gas heating in the hydrogen ionization front) or shallower depths (effective gravity due to continuum radiation pressure).

The work presented in this paper forms a basis for further development of dynamic photoionization models that will be covered in two following papers. In the first, the inclusion of chemistry and dissociation/formation processes allows a unified treatment of the entire flow from cold, molecular gas, through the PDR, and into the H II region. Previous work by Stoerzer & Hollenbach (1998) indicates that advection can have a significant effect on the position of the molecular hydrogen dissociation front. In the second, divergent, transonic flows from strong-D fronts are modeled, which can explain the kinematic observations discussed in item 5 above.

We are most grateful to Bob O'Dell for providing the *HST* WFPC2 mosaics of the Orion Nebula in various optical emission lines and to Torsten Elwert for useful comments on a draft of the manuscript. We are grateful for financial support from NASA Astrophysics Theory Program grant NAG 5-12020, *HST* archival program AR 10316, and DGAPA-UNAM, Mexico, grant PAPIIT IN115202. In addition, W. J. H. and S. J. A. are grateful to the University of Leeds, UK, for hospitality during a year's sabbatical visit, supported by grants from DGAPA-UNAM. R. J. R. W. acknowledges support from a PPARC Advanced Fellowship while this work was developed and thanks Cardiff University for hosting him during the period of this grant. R. J. R. W. also thanks the Ministry of Defense, UK, for support while this work was completed.

APPENDIX A

SIMPLIFIED ANALYTIC MODEL FOR WEAK-D IONIZATION FRONTS

In this appendix we develop a simple analytic model for a plane-parallel ionization front in order to explore the most important effects of advection on the front structure. The principal simplification involved is the assumption that the gas temperature, T , follows a unique prescribed function of the hydrogen ionization fraction, x . It is a generic property of ionization fronts that the temperature tends to increase as one passes from the neutral to the ionized side of the front. In the analytic model, we assume that the increase is monotonic and has the form

$$T(x) = T_m - \frac{1 - x^{\beta_T}}{1 + x^{\beta_T}} (T_m - T_0), \quad (\text{A1})$$

where T_m is the limiting temperature in the ionized gas ($x \rightarrow 1$), T_0 is the limiting temperature on the far neutral side ($x \rightarrow 0$), and β_T is a parameter controlling the sharpness of the transition. In reality, for moderate to high ionization parameters, the hardening of the radiation field as one approaches the ionization front causes the temperature to have a maximum for x somewhat less than unity (see, e.g., Fig. 9b). However, for weak-D fronts, equation (A1) is sufficient to capture the main effects of advection.⁴ Furthermore, it turns out that advection itself will modify the $T(x)$ curve (see § 4), but again we ignore this complication in the analytic model. We further simplify the model by only considering the ionization of hydrogen and ignoring the effects of radiation pressure, dust, and magnetic fields.

With these approximations, the gas pressure is given by

$$P = n(1 + x)kT, \quad (\text{A2})$$

where n is the hydrogen number density. For a static front, the gas pressure will be constant, so it is a simple matter to calculate the variation of gas density, n , and electron density, n_e , with ionization fraction:

$$\frac{n(x)}{n_m} = \frac{2}{1 + x} \left[\frac{T(x)}{T_m} \right]^{-1}, \quad n_e(x) = xn(x). \quad (\text{A3})$$

These are all plotted by solid lines in Figure 18. In this and all following examples, we use temperature-law parameters of $\beta_T = \frac{1}{3}$ and $T_0/T_m = 0.02$, which agrees within 10%–20% with the temperature profiles of all the weak-D models in § 4. It can be seen that, although the gas density declines with increasing x , the electron density is a monotonically increasing function of x (this is always true, whatever the value of β_T).

In order to calculate the structure of a nonstatic, dynamic front, it is necessary to consider the conservation of mass and momentum, which are given, in plane-parallel geometry, by

$$nm_H v = \Phi_0, \quad P + nm_H v^2 = \Pi_0, \quad (\text{A4})$$

where v is the gas velocity and Φ_0 and Π_0 are the (constant) mass and momentum fluxes. It is convenient to define the dimensionless variable ϕ :

$$\phi \equiv \frac{\Pi_0}{2c\Phi_0}, \quad (\text{A5})$$

which, by equation (A4), is related to the isothermal Mach number ($\mathcal{M} \equiv v/c$) via

$$\phi = \frac{1}{2} \left(\mathcal{M} + \frac{1}{\mathcal{M}} \right), \quad (\text{A6})$$

with the inverse relation

$$\mathcal{M} = \phi \pm (\phi^2 - 1)^{1/2}, \quad (\text{A7})$$

in which the minus sign applies to a subsonic flow and the plus sign to supersonic flow.

⁴ For D-critical/strong-D fronts, on the other hand, the position of the temperature maximum is critical.

FIG. 18.—Weak-D solutions with various maximum Mach numbers $\mathcal{M}_m$.

Equation (A6) shows that $\phi \geq 1$ everywhere and that $\phi = 1$ corresponds to the sonic point: $\mathcal{M} = 1$. A given ionization front can be characterized by the parameter ϕ_m , which is the minimum value of ϕ anywhere in the front. This is achieved when the isothermal sound speed c attains its *maximum* value c_m , and, in the case of the weak-D fronts considered here, corresponds to the maximum value of the (subsonic) Mach number: $\mathcal{M}_m$.⁵ For a temperature profile such as equation (A1), c_m occurs at $x = 1$ and the sound speed varies with x as

$$c(x) = c_m \left[\frac{T(x)}{T_m} \frac{1+x}{2} \right]^{1/2}. \quad (\text{A8})$$

It can be seen that all weak-D fronts with a given $T(x)$ form a one-parameter family, characterized by their maximum Mach number $\mathcal{M}_m$. For a given $\mathcal{M}_m$, the corresponding ϕ_m can be calculated from equation (A6), and then from equation (A5) we have $\phi(x) = \phi_m c_m / c(x)$, which can be inserted into equation (A7) to give $\mathcal{M}(x)$, from whence we also have $v(x) = \mathcal{M}(x)c(x)$, $n(x) = n_m \mathcal{M}_m c_m / v(x)$, and $n_e(x) = x n(x)$. Hence, the full structure of the ionization front as a function of x can be found algebraically. The results are plotted in Figure 18 for various weak-D fronts between $\mathcal{M}_m = 0$ and 0.99.

For $\mathcal{M}_m = 0.2$, the velocities are everywhere very subsonic and the density structure is hardly any different from the static case (*bottom panels*). In this regime, the velocity rises approximately as $u \simeq c^2 \mathcal{M}_m / c_m \propto (1+y)T(y)$. There is hence an initial brisk acceleration for $y < 0.05$, driven largely by the increase in T , followed by a slower, almost constant, acceleration, driven largely by the increase in ion fraction. For higher $\mathcal{M}_m$, the gas density contrast between the ionized and neutral sides increases, and for $\mathcal{M}_m > 0.7$ this causes there to be a maximum in n_e at an intermediate value of y . Solutions with $\mathcal{M}_m > 0.7$ also show a second episode of steep acceleration as $y \rightarrow 1$.

In order to apply these results, it is necessary to find the mapping between the ionization fraction, x , and physical position within the ionization front. For this, it is necessary to introduce more parameters than have so far been considered. The ionized gas is assumed to have an inner boundary $z = 0$, at which the ionizing flux is F_0 , and with z being the distance to the ionized gas, measured from the illuminated face, in the direction of decreasing x . Globally, the flux of ionizing photons at $z = 0$ must be balanced by the recombinations per unit area, integrated throughout the structure, *plus* the (constant) flux of hydrogen nuclei through the front:

$$F_0 = \frac{\Phi_0}{m_H} + \int_0^\infty \alpha(x) x^2 n^2 dz, \quad (\text{A9})$$

⁵ For R-type fronts, on the other hand, $\mathcal{M}_m$ is the minimum Mach number. For D-critical and strong-D fronts, $\mathcal{M}_m = 1$ and is no longer a turning point in $\mathcal{M}$, not even a point of inflexion, although ϕ_m is still a maximum in ϕ .

where α is the recombination coefficient, which we approximate as a power law in the gas temperature, $\alpha = \alpha_m (T/T_m)^{-1}$. The global importance of advection on the ionization balance can be characterized by the relative magnitude of the two terms on the right-hand side of this equation, so we define a dimensionless “global advection parameter”

$$\lambda_{\text{ad}} \equiv \frac{\Phi_0}{F_0 m_{\text{H}} - \Phi_0}. \quad (\text{A10})$$

We also define a characteristic “Strömgren distance” as

$$z_0 \equiv \frac{1 + \lambda_{\text{ad}}}{\alpha_m n_m^2} \int_0^\infty \alpha x^2 n^2 dz, \quad (\text{A11})$$

in terms of which equation (A9) becomes

$$F_0 = \alpha_m n_m^2 z_0. \quad (\text{A12})$$

At each point, z , within the structure we also have the *local* ionization equation:

$$\alpha x^2 n^2 - F(1 - x)n\bar{\sigma} = \frac{d}{dz}(xnv) = \frac{\Phi_0}{m_{\text{H}}} \frac{dx}{dz}, \quad (\text{A13})$$

where F is the local value of the ionizing flux and $\bar{\sigma}$ is the mean photoabsorption cross section for ionizing photons, evaluated by integrating over the ionizing spectrum at that point. The attenuation of the ionizing radiation is expressed by

$$\frac{dF}{dz} = -\bar{\sigma}n(1 - x)F. \quad (\text{A14})$$

Equations (A13) and (A14) can be reexpressed in dimensionless form as

$$\frac{dx}{d\bar{\tau}} = \frac{1}{\mathcal{M}_m \xi_{\text{ad}}} \left[\frac{\tilde{\alpha} \tilde{n} x^2}{\tilde{\sigma}(1 - x)} - \tau_* e^{-\bar{\tau}} \right] \quad (\text{A15})$$

and

$$\frac{d\tilde{z}}{d\bar{\tau}} = [\tau_* \tilde{\sigma} \tilde{n}(1 - x)]^{-1}, \quad (\text{A16})$$

with dimensionless variables

$$\tilde{z} \equiv \frac{z}{z_0}, \quad \tilde{n} \equiv \frac{n}{n_m}, \quad \tilde{\alpha} \equiv \frac{\alpha}{\alpha_m}, \quad \tilde{\sigma} \equiv \frac{\bar{\sigma}}{\bar{\sigma}_0}, \quad \bar{\tau} \equiv -\ln \frac{F}{F_0}.$$

Equations (A15) and (A16) also make use of two dimensionless parameters:

$$\tau_* \equiv n_m \bar{\sigma}_0 z_0 \quad (\text{A17})$$

and

$$\xi_{\text{ad}} \equiv \frac{c_m \bar{\sigma}_0}{\alpha_m}, \quad (\text{A18})$$

in terms of which the global advection parameter, λ_{ad} , can be expressed as

$$\lambda_{\text{ad}} = \frac{\xi_{\text{ad}} \mathcal{M}_m}{\tau_* - \xi_{\text{ad}} \mathcal{M}_m}, \quad (\text{A19})$$

and whose significance is explored more fully in § 2. These two differential equations can be integrated numerically to find the full solution for the ionization front structure in physical space. Note that for the static case ($\mathcal{M}_m = 0$), equation (A15) is undefined and we instead have simply that the term in square brackets is zero.

FIG. 19.—Line emissivity structure of static and dynamic ionization fronts ($\tau_* = 30$), in which different line types correspond to a generic recombination line (solid line), optical collisional line of an ionized species (dashed line), and optical collisional line of a neutral species (dot-dashed line). The set that peaks to the right is from a static model ($\mathcal{M}_m = 0.0$), while the set that peaks to the left is from a nearly D-critical model ($\mathcal{M}_m = 0.99$).

We now present sample results from solving equations (A15) and (A16) using parameters appropriate to an H II region illuminated by an O star. We approximate the reduction in photoabsorption cross section due to the hardening of the ionizing radiation field as $\tilde{\sigma} \simeq [1 + 0.2(\tilde{\tau} + \tilde{\tau}^2)]^{-1}$. This is a good fit to the exact result from assuming the ionizing spectrum of a 40,000 K blackbody and $\sigma(\nu) \propto \nu^{-3}$, from which we also obtain $\tilde{\sigma}_0 = 0.505\sigma(\nu_0) \simeq 3 \times 10^{-18} \text{ cm}^2$. We also assume $\alpha_m = 2.6 \times 10^{-13} \text{ cm}^3 \text{ s}^{-1}$ and $c_m = 10 \text{ km s}^{-1}$, which give $\xi_{\text{ad}} = 11.5$. For the parameter τ_* , we adopt the values 30 and 3000, corresponding to a low and a high ionization parameter, respectively, with the second being more representative of typical H II regions. The results are shown in Figure 3. In each case, curves of the electron density and gas velocity are shown for models with (right to left) $\mathcal{M}_m = 0.0, 0.2, 0.5, 0.7, 0.9$, and 0.99. For $\tau_* = 30$ the direct effects of advection are considerable, since $\lambda_{\text{ad}} = 0.64\mathcal{M}_m$, so that for the higher Mach numbers a substantial fraction of the incident ionizing flux is consumed by ionization of new atoms, which pushes the ionization front to the left.

It can also be seen that the advection decreases the width of the ionization front. In the static front, the width is determined by the mean free path of ionizing photons in the partially ionized gas, which gives $\delta z \sim (n\sigma)^{-1}$, whereas in the advective fronts the ionization fraction at a given value of the ionizing flux is smaller, leading to a sharper front (4 times narrower in the near-critical case). In addition, the electron density in the advective models has a peak at the ionization front, which is not seen in the static models. For $\tau_* = 30$, we have $\lambda_{\text{ad}} = 0.0038\mathcal{M}_m$, so the direct effects of advection on the global properties of the model should be very small. Nonetheless, the ionization front position varies by about 5% between the static model and the $\mathcal{M}_m = 0.99$ model, which is due to the effect of the electron density peak.

In order to investigate the effects of advection on the emission-line properties of the nebula, we consider a generic recombination line with emissivity

$$\eta_{\text{rec}}(x) = A_{\text{rec}} n_e n_{j+1} T^{\beta_{\eta}}, \quad (\text{A20})$$

where n_{j+1} is the number density of the recombining ion, and a generic collisionally excited line with emissivity

$$\eta_{\text{col}}(x) = \frac{A_{\text{col}} n_e n_j}{1 + B_{\text{col}} n_e T^{-1/2}} \frac{e^{-E/kT}}{\sqrt{T}}, \quad (\text{A21})$$

where E is the excitation energy of the upper level and B_{col} is the collisional de-excitation coefficient. The ion density can be assumed to be $n_j \propto n_e = xn$ for singly ionized ions and $n_j \propto (1-x)n$ for neutral atoms.

The results are shown in Figure 19, which compares the line emissivities as a function of radius for the $\tau_* = 30$ model at two values of $\mathcal{M}_m$: 0.0 and 0.99. The total emission from all the lines is significantly reduced in the nearly D-critical model with respect to the static model as a result of the smaller depth of the ionized zone. On the other hand, the relative intensities integrated over the entire structure change by less than 10%. The peak of the neutral collisional line is much sharpened in the advective model as a result of the narrowing of the ionization front. In addition, the singly ionized collisional line and the recombination line both show peaks in their emissivity at the ionization front, which are due to the electron density peak there (see Fig. 3).

The line emissivity can be combined with the velocity structure of the front to create synthetic emission line profiles. We assume that the front is observed face-on from the ionized side, so that the lines are all blueshifted with respect to the neutral gas, which is assumed to be stationary. We calculate the emergent intensity profile, $I(u)$, of an emission line ignoring any optical depth effects:

$$I(u) = \int_0^\infty \eta(z) \exp\left\{-\frac{[v(z) - u]^2}{2\Delta^2(z)}\right\} dz, \quad (\text{A22})$$

FIG. 20.—Predicted line profiles from analytic ionization front model for $\tau_* = 30$ (left) and 3000 (right). Top panels show a generic optical collisional line of a neutral species, while bottom panels show the same for a singly ionized species. Different line types correspond to $\mathcal{M}_m = 0.0$ (solid line), 0.5 (dashed line), and 0.99 (dot-dashed line).

where u is the observed velocity and Δ is the thermal Doppler width, calculated at each point in the structure assuming typical atomic weights of 16 for the collisional neutral line, 14 for the collisional ionized line, and 1 for the recombination line.

The resultant profiles are shown in Figure 20 for the collisional lines.⁶ The increasing blueshift of both lines with increasing maximum Mach number is evident. For the singly ionized line, there is hardly any dependence of line width on the advection strength because most of the emission comes from the almost fully ionized gas, which shows only small velocity gradients. For the neutral line, on the other hand, the nearly critical model shows a much broader, double-humped line. The redder component of the line is due to the emissivity peak around $x = 0.5$ and is little changed between $\mathcal{M}_m = 0.5$ and 0.99, whereas the bluer component in the $\mathcal{M}_m = 0.99$ model comes from the nearly fully ionized gas and is hence relatively stronger in the model with the higher ionization parameter ($\tau_* = 3000$).

The behavior of the mean velocity, $\bar{v}$, and rms⁷ velocity width, σ , of the collisional lines as a function of $\mathcal{M}_m$ is shown in Figure 21.

APPENDIX B

TREATMENT OF IONIZATION LADDERS

The rate of change of the fractional abundance of a particular ionization state is given by

$$\frac{\partial n_i}{\partial t} = G_i + \sum_{j \neq i} R_{j \rightarrow i} n_j - n_i \left(S_i + \sum_{j \neq i} R_{i \rightarrow j} \right), \quad (\text{B1})$$

where the $R_{i \rightarrow j}$ are the rates for ionization (where j is a higher state than i) and recombination (where j is a lower state than i). G_i and S_i cater for processes not included within the ionization ladder and are, respectively, the source of ions from such processes and the sink rate into them.

⁶ The recombination line has a very similar emissivity profile to the singly ionized collisional line, and the low atomic weight only serves to smear out the details of the line profile.

⁷ For a Gaussian line profile the FWHM, Δv , is related to the rms width by $\Delta v = 2.306\sigma$.

FIG. 21.—Predicted mean velocities and rms widths (in km s^{-1}) of collisionally excited lines from the analytic ionization front model as a function of $\mathcal{M}_m$ for $\tau_* = 30$ (left) and 3000 (right).

In previous versions, Cloudy treated the ionization ladders in isolation, with $G_i = S_i = 0$, and $R_{ij} \neq 0$ only for processes coupling neighboring ionization states,

$$R_{i \rightarrow j} = \begin{cases} \mathcal{R}_i, & j = i + 1, \\ \mathcal{I}_j, & i = j + 1, \\ 0, & \text{otherwise.} \end{cases} \quad (\text{B2})$$

In this case, equation (B1) in equilibrium ($d/dt \rightarrow 0$) gives the equations

$$0 = n_2 \mathcal{R}_1 - n_1 \mathcal{I}_1, \quad (\text{B3})$$

$$0 = n_3 \mathcal{R}_2 + n_1 \mathcal{I}_1 - n_2 (\mathcal{I}_2 + \mathcal{R}_1), \quad (\text{B4})$$

$$0 = n_4 \mathcal{R}_3 + n_2 \mathcal{I}_2 - n_3 (\mathcal{I}_3 + \mathcal{R}_2), \quad (\text{B5})$$

$$0 = n_{N-1} \mathcal{I}_{N-1} - n_N \mathcal{R}_{N-1}, \quad (\text{B6})$$

for the abundances n_i of an N -state ionization ladder. These equations yield a simple expression for the relative abundances of neighboring ionization states,

$$n_{i+1}/n_i = \mathcal{I}_i/\mathcal{R}_i. \quad (\text{B7})$$

The overall abundance of each ionization level can be found using this relation together with a sum rule for the conserved total abundance of the species.

This analysis does not apply if we require a time-dependent solution, or there are more complex interactions between levels (such as the Auger effect) or external sources and sinks of ions (resulting, for example, from molecular processes).

If we assume a general form for all these additional terms, we are left with a computationally expensive $N \times N$ matrix problem to solve. However, the largest coefficients in the matrix derived from equation (B1) will either be the ionization and recombination rates, for which we know that a simple solution is possible, or possibly the time-dependent terms (as, for instance, in nonequilibrium cooling behind a shock). This suggests that we should be able to find a solution to the ladder equations efficiently using iterative techniques.

We rewrite equation (B1) as

$$\sum_j A_{ij} n_j = \sum_j (\hat{A}_{ij} + \tilde{A}_{ij}) n_j = b_j. \quad (\text{B8})$$

We separate the matrix A_{ij} into two parts, a tridiagonal component $\hat{A}_{ij}$ and the remainder $\tilde{A}_{ij}$. The components of $\tilde{A}_{ij}$ will in general be far smaller than those of $\hat{A}_{ij}$, so we can use the iterative scheme

$$\mathbf{n}^{n+1} = \hat{\mathbf{A}}^{-1} (\mathbf{b} - \tilde{\mathbf{A}} \cdot \mathbf{n}^n) = \mathbf{n}^n + \hat{\mathbf{A}}^{-1} (\mathbf{b} - \mathbf{A} \cdot \mathbf{n}^n) \quad (\text{B9})$$

to converge to the solution to the ionization state. In particular, in the nonlinear system we are treating, the coefficients in $\mathbf{A}$ and $\mathbf{b}$ will themselves be functions of the ionization state of the gas, and so it suffices to take a single step of the iterative scheme given by equation (B9) before these values are updated.

There is one problem with this treatment. In the limit of small advection, $\hat{\mathbf{A}}^{-1}$ becomes singular. In this limit, the solution we require is the null eigenvector of $\mathbf{A}$, and as in the previous treatment we can set its magnitude using an additional normalization constraint. However, the rounding error in the summation of ionization and recombination terms on the diagonal of $\mathbf{A}$ can lead to the numerical solution of equation (B9) having negative abundances for states that are substantially less abundant than their neighbors. The ease with which the solution given by equation (B7) is found suggests that this is not unavoidable. By rewriting the standard tridiagonal solver in Press et al. (1992) to treat matrices in the particular form of $\hat{\mathbf{A}}$ (and providing the ionization, recombination, and diagonal sink vectors to this revised algorithm without summation), a near cancellation is avoided. The resulting scheme gives solutions that are manifestly positive, given the physical limits on the signs of the various vector elements.

APPENDIX C

MAGNETIC FIELD

Magnetic field effects can now be included in Cloudy simulations by specifying the magnetic field strength and geometry at the illuminated face. Both an ordered field and a “tangled” field may be specified, although currently the ordered field is restricted to plane-parallel slab models with advection. The tangled field may be used in any geometry and with advective or static models.

The tangled field is assumed to provide an isotropic magnetic pressure. In addition to the field strength at the illuminated face, $B_{\text{tangled},0}$, the effective magnetic adiabatic index, γ_{mag} , must also be specified. This determines the response of the field to compression of the gas:

$$B_{\text{tangled}} = B_{\text{tangled},0} \left(\frac{\rho}{\rho_0} \right)^{\gamma_{\text{mag}}/2}. \quad (\text{C1})$$

A value $\gamma_{\text{mag}} = 0$ implies a constant magnetic field strength throughout the model, whereas $\gamma_{\text{mag}} = 4/3$ (the default) corresponds to conservation of magnetic flux and is what would be expected in the absence of dynamo action or magnetic reconnection.

For the ordered field one must specify a component B_z that is parallel to the integration direction through the slab and a component B_t that is transverse to the integration direction. The parallel component B_z is constant throughout the slab, while the transverse component is a function of the varying gas velocity, v :

$$B_t = B_{t,0} v_0 - v_A^* v - v_A^*, \quad (\text{C2})$$

where v_A^* is a characteristic speed (Williams & Dyson 2001),

$$v_A^* = \frac{B_z^2}{4\pi\rho_0 v_0}. \quad (\text{C3})$$

Magnetic pressure is included in the gas equation of state, having the form

$$P_{\text{mag}} = \frac{B_{\text{tangled}}^2}{8\pi} + \frac{B_t^2 - B_z^2}{8\pi} \text{ dynes cm}^{-2}. \quad (\text{C4})$$

The magnetic contribution to the enthalpy density is given by

$$w_{\text{mag}} = \frac{\gamma_{\text{mag}}}{\gamma_{\text{mag}} - 1} \frac{B_{\text{tangled}}^2}{8\pi} + \frac{B_t^2 + B_z^2}{4\pi} \text{ dynes cm}^{-2}. \quad (\text{C5})$$
