Abstract

Lipid Phosphate phosphatase 3 (LPP3), encoded by the Plpp3 gene, is an enzyme that dephosphorylates the bioactive lipid mediator lysophosphatidic acid (LPA). To study the role of LPP3 in the myocardium, we generated a cardiac specific Plpp3 deficient mouse strain. Although these mice were viable at birth in contrast to global Plpp3 knockout mice, they showed increased mortality ~8 months. LPP3 deficient mice had enlarged hearts with reduced left ventricular performance as seen by echocardiography. Cardiac specific Plpp3 deficient mice had longer ventricular effective refractory periods compared to their Plpp3 littermates. We observed that lack of Lpp3 enhanced cardiomyocyte hypertrophy based on analysis of cell surface area. We found that lack of Lpp3 signaling was mediated through the activation of Rho and phospho-ERK pathways. There are increased levels of fetal genes Natriuretic Peptide A and B (Nppa and Nppb) expression indicating myocardial dysfunction. These mice also demonstrate mitochondrial dysfunction as evidenced by a significant decrease (P < 0.001) in the basal oxygen consumption rate, mitochondrial ATP production, and spare respiratory capacity as measured through mitochondrial bioenergetics. Histology and transmission electron microscopy of these hearts showed disrupted sarcomere organization and intercalated disc, with a prominent disruption of the cristae and vacuole formation in the mitochondria. Our findings suggest that LPA/LPP3-signaling nexus plays an important role in normal function of cardiomyocytes.

Lipid phosphate phosphatase
Lyosphosphatidic acid

1. Introduction

The phospholipid phosphatase 3 (PLPP3) gene encodes LPP3, an integral membrane protein which is Mg2+ dependent and N-ethylmaleimide insensitive enzyme responsible for the dephosphorylation of lipid phosphates such as phosphatidic acid (PA) and lysosphosphatidic acid (LPA). It is robustly expressed in the heart [1]. Subcellularly, LPP3 is located in the plasma membrane [2], the endoplasmic reticulum (ER), Golgi complex and endosomes [3,4]. Global knockout of Plpp3 (formerly Ppp2h) in mice leads to embryonic lethality around embryonic age 10 due to defects in the development of extraembryonic vasculature [5]. In addition, we have demonstrated that deficiency of endothelial cell specific LPP3 leads to increased vascular permeability and defective cardiovascular development resulting in embryonic lethality [6] and knockout of Plpp3 in both endothelial or smooth muscle cells shows enhanced inflammation and permeability [6,7]. These findings imply that LPP3 expression is essential for normal prenatal cardiovascular development and, in adult mice, LPP3 normally functions to maintain the vascular integrity and attenuate inflammation.

Although other functions are likely, LPP3 is a key regulator of the bioactive lipid LPA and terminates its signaling function through dephosphorylation. LPA plays a well-known role in atherosclerotic disease. A six-fold increase in serum LPA concentration has been observed following acute myocardial infarction in patients (1.66 mg/L vs 10.43 mg/L, P < 0.001) [8]. We have shown that exogenous

administration of LPA increases heart rate and left ventricular pressure in vivo [9]. Furthermore, LPA has been shown to induce cardiomyocyte hypertrophy in cell culture models [10,11]. These findings suggest a critical role for LPA-mediated signaling in the myocardium. Interruption of LPA signaling in the myocardium may be an important factor in protecting the heart against insult and injury. As conventional deletion of the Plpp3 results in severe embryonic developmental abnormalities [5], a specific role for the LPP3 enzyme in adult myocardium remains unknown. Therefore, we used the Cre/loxP system to delete Plpp3 specifically in cardiomyocytes. This strategy resulted in mice which do not express LPP3 in the heart. Here, we characterize these animals in order to understand the role of LPP3 in the adult myocardium under physiological conditions. Our findings indicate that LPP3 serves as an intrinsic negative regulator of LPA mediated cardiomyocyte hypertrophy. These findings suggest that LPP3 is crucial in maintaining the normal cardiac homeostasis and plays an important role in the protection of cardiomyocytes in vivo.

2. Material and methods

2.1. Generation of mice with cardiac-specific deletion of Plpp3

The production and initial characterization of mice carrying a conditional allele of Plpp3 (Plpp3flox) have previously been described [6,7]. Plpp3flox mice were backcrossed for >10 generations into the C57Bl/6 background. These mice were then crossed with C57Bl/6 mice expressing Cre recombinase under the control of the cardiac-specific alpha-mysin heavy chain promoter (Myh6-Cre) [12] to obtain congenic Plpp3flox mice.

The mice survived in the expected numbers. Mating of homozygous Plpp3flox with Plpp3flox mice yielded 50% Plpp3flox offspring with less than 2% mortality at birth. Mice were housed in cages with HEPA-filtered air in rooms on 12-h light cycles and fed Purina 5058 rodent chow ad libitum. Systolic blood pressure and heart rate were measured for five consecutive days noninvasively in conscious mice using the CODA blood pressure analysis tail-cuff system (Kent Scientific Corporation, Torrington, CT) daily after training for one week. All procedures conformed to the recommendations of Guide for the Care and Use of Laboratory Animals (Department of Health, Education, and Welfare publication number NIH 78-23, 1996), and were approved by the Institutional Animal Care and Use Committee. Neonatal cardiomyocytes were isolated from the Plpp3flox with Plpp3flox mice as described previously [13] (Supplementary video shows the beating neonatal cardiomyocyte derived from Plpp3flox mice).

Supplementary material related to this article can be found online at http://dx.doi.org/10.1016/j.redox.2017.09.015.

2.2. ECGs and electrophysiology studies

Surface resting ECGs and electrophysiology studies were performed on male 12-week-old Plpp3flox control mice. Mice were anesthetized with isoflurane (2% for induction and 1.5% for maintenance of anesthesia; Apollo Tech 3 Vaporizer; NorVap). During EP studies the mouse body temperature was monitored by an intra-rectal probe and controlled using mouse pad circuit board equipped with a heating element (Rodent Surgical Monitor, Indus Instruments, USA). All studies were performed at 37.0 ± 0.5 °C. We used a Millar 1.1F octopolar EP catheter (EPR-800; Millar Instruments) inserted via a cut down of the internal right jugular vein. The catheter was advanced to the right atrium and ventricle using electrogram guidance and pacing capture to verify intracardiac position. A computer-based data acquisition system (PowerLab 16/30; ADI Instruments) was used to record a 1-lead body surface ECG and up to 4 intracardiac bipolar electrograms (LabChart Pro software, version 7; AD Instruments). In brief, the right ventricular pacing was performed using 2 ms current pulses delivered by an external stimulator (STG-3008 FA; Multi Channel Systems). Ventricular effective refractory period (VERP) or ventricular tissue refractoriness and ventricular arrhythmia inducibility were assessed by single extra stimulation or burst pacing using an automated stimulator. To determine VERP, the single ventricular extra stimulus was placed at a pacing drive of 100 ms. A drive train of eight paced beats (S1 × 8) followed by delivery of a single extra stimulus (S2) was given until ventricular stimuli failed to result in ventricular depolarization. To induce ventricular tachycardia, the triple extra stimulation technique was utilized first. Triple extra stimuli were delivered with S2, S3 or S4 extra stimuli brought down to a minimum coupling interval of 30 ms (1). If this maneuver failed to induce ventricular tachycardia (VT), we then performed burst pacing. Burst pacing started at a 40 ms cycle length, decreasing by 2 ms every 2 s to a cycle length of 20 ms. Burst pacing was repeated one minute after the previous burst concluded or the termination of VT. If the mice were non-inducible for VT, we then repeated the above maneuvers after an IP injection of Isoproterenol (1 ng/g). Ventricular tachycardia was defined as 4 consecutive beats of ventricular premature depolarizations or more [15].

2.3. RNA isolation and quantitative PCR

Human and mouse Plpp3 lentiiruses were derived as described previously [7]. Total RNA was extracted from heart tissues and primary cardiomyocytes using the RNeasy mini kit (Qiagen, Chatsworth, CA) following manufacturer’s instructions. cDNA was prepared with Multi-scribe reverse transcriptase enzyme (High-Capacity cDNA Archive Kit; Applied Biosystems, Foster City, CA), and mRNA expression was measured in a RT-PCR reaction using TaqMan® gene expression assays and TaqMan® Universal PCR Master Mix No Amp Erase® (Applied Biosystems) on an ABI 7500 Fast Real-Time PCR System (Applied Biosystems). Threshold cycles (CT) were determined by an in-program algorithm assigning a fluorescence baseline based on readings prior to exponential amplification. An embryo RNA standard was used as a positive control. Fold change in expression was calculated using the 2−ΔΔCT method using 18 S RNA as an endogenous control [7].

2.4. Quantification of intracellular superoxide and LPA by mass spectrometry

Dihydroethidium (DHE, Invitrogen), which exhibits blue fluorescence in the cytosol until oxidized, was used to estimate the levels of superoxide after LPA treatment. The procedures for DHE were conducted using a FACScan protocol using a flow cytometry. For the quantitation of LPA molecular species, we used HPLC-tandem mass spectrometry as previously described [6,7]. Analysis of LPA was carried out using Waters Acquity UPLC coupled with a XEVO TQ-MS ESI mass
spectrometer. Sphingosine-1-phosphate (S1P) was used as an internal standard. S1P and LPA (Avanti Polar Lipid, Inc.) were separated using a Waters BEH C18 column, 1.7 µm, 2.1 × 50 mm column. The mobile phase consisted of 60/40 acetonitrile/water with formic acid (0.1%) and 5 mM ammonium formate (0.1%) as solvent A and 95/5 acetonitrile/water with formic acid (0.1%) and 5 mM ammonium formate (0.1%) as solvent B. For the analysis of S1P and LPA the separation was achieved using gradient of 0–100% B in the next 4 min, maintained at 100% B for the next 6 min and equilibrated back to the initial conditions in 5 min. The flow rate was 0.3 ml/min with a column temperature of 40 °C. The sample injection volume was 5 µL. The positive electrospray ionization mode for S1P and negative electrospray ionization mode for LPA were selected. The optimal ion source conditions were determined by S1P and LPA with a capillary voltage 3.82 V, cone voltage 17 V, desolvation temperature 450 °C, desolvation gas flow 1000 L/h, source temperature 150 °C, collision energy 10 V and ion source temperature was 150 °C. S1P was detected by positive mode [M]+ 365.2 and LPA was detected by negative mode [M-H] − 421.2 of full scan mode.

2.6. Mitochondrial isolation

Heart mitochondria were isolated as described previously by Mela and Seitz [16]. Briefly, the hearts were collected, washed in ice-cold isolation buffer (0.225 M mannitol, 0.075 M sucrose, 1 mM EGTA, pH 7.4), and was homogenized at 500 rpm with a chilled Teflon pestle in a glass cylinder with 10 strokes. The homogenate was centrifuged at 480 × g at 4 °C for 5 min. The pellet was rinsed with 0.5 ml of the isolation buffer with gentle shaking to remove the “fluffy layer” (damaged mitochondria) on top of the pellet. The wall of the centrifuge tube was cleaned with cotton swabs to remove lipids. The pellet was washed by
gentle resuspension in 3 ml isolation buffer using the smooth surface of a glass rod and centrifuged at 7700 × g at 4 °C for 10 min. At every step, the supernatant was saved to check again for leakage from the mitochondria. The resulting mitochondria were collected for further analysis. The purity of mitochondria was examined using Lamin B (a nuclear protein) and IκB-α (a cytoskeletal protein) as indicators by western blotting. Protein content in the lysate was determined by BCA protein assay (Pierce, Rockford, IL).

2.7. Mitochondrial bioenergetics

Oxygen consumption was determined using the Seahorse Fig. 2. Cardiac dysfunction exhibited in Plpp3Δ mice. A) Kaplan-Meier analysis of survival probabilities for the Plpp3Δ (n = 36) vs the Plpp3fl (n = 38) animals (left) and the hearts of the 8-month-old Plpp3Δ mice are significantly larger than the heart of the Plpp3fl mice (right). B) Representative hematoxylin and eosin-stained hearts (LV) from Plpp3Δ as compared to their Plpp3fl littermates with immersion fixation. C) Masson’s trichrome stained Plpp3Δ hearts (LV) show increased density of connective tissue collagen matrix deposition. All analyses were carried out with 8-month-old mice. Scale bars 100 µm. D) Transmission electron micrograph of the 8-month-old myocardium (LV) from Plpp3Δ as compared to their Plpp3fl littermates. Plpp3Δ myocardium showed distorted (ID) intercalated disc with damaged mitochondria (Mi). Mitochondrial insert showing disorganization of cristae (C), vacuole formation (V) and amorphous matrix densities in Plpp3Δ as compared to Plpp3fl. Bar denotes 500 nm.
Extracellular Flux (XF-24) analyzer (Seahorse Bioscience, Chicopee, MA). The XF-24 measures the concentration of oxygen and free protons in the medium above a monolayer of cells in real-time. Thus, the rates of oxygen consumption and proton production can be measured across several samples at a time. To allow comparison between experiments, data are presented as oxygen consumption rate (OCR) in pmol/min/µg.

Fig. 3. Echocardiographic indices of Plpp3Δ mice. A) Bar graph shows percentage changes in fractional shortening (%FS) and ejection fraction (%EF) in Plpp3Δ mice compared to their Plpp3fl littermates (n = 6) as measured echocardiography. B) Bar graph show representative hearts with an HW/BW ratio, left ventricular (LV) mass, diastolic left ventricular internal diameter (LVIDd); and systolic left ventricular internal diameter (LVIDs). C) Electrophysiology studies show inducible ventricular tachycardia (VT) and ventricular effective refractory periods (VERP) were significantly elevated in Plpp3Δ mice as compared to their Plpp3fl littermates (n = 6). D) Real-time RT-PCR shows fold differences in mRNA of Nppa and Nppb with the value of Plpp3fl defined as 1 (mean ± SD, n = 4 each). *P < 0.05 by t-test vs control. E) Steady state plasma levels of total LPA from the circulation of live mice from Plpp3fl control and Plpp3Δ were measured by LC-MS/MS. Values are expressed as a fold increase over control and graphed as mean ± SD from n = 5 animals per time point. *P < 0.01 compared to control.
protein and the extracellular acidification rate (ECAR) in mEq/min/μg protein. Neonatal cardiomyocytes were seeded at 100,000 cells/well into gelatin-coated Seahorse Bioscience XF microplates, cultured in the presence or absence of 2 g/L n-glucose, and then centrifuged to adhere to the bottom of the wells. OCR was measured four times and plotted as a function of cells under the basal condition followed by the sequential addition of oligomycin (1 μg/ml, an inhibitor of mitochondrial ATP synthase) was injected into the XF medium to estimate the OCR coupled to ATP synthesis and represented as ATP-linked. The residual oligomycin/OCR minus the non-mitochondrial OCR (after antimycin A treatment) can be attributed to proton leak. FCCP (0.5 μM), an uncoupler, is added to determine the maximal OCR, followed by antimycin (1 μM), an inhibitor of mitochondrial respiration, to determine non-mitochondrial sources of oxygen consumption. The ATP-linked OCR was calculated as the difference between the basal OCR and the OCR measured after the addition of oligomycin. The OCR maximal capacity was the direct rate measured after the addition of FCCP minus non-mitochondrial respiration. Spare respiratory capacity is a measure of the amount of ATP that can be produced under energetic demand and can be calculated as the difference between the maximum rate of respiration and the basal. The OCR values were normalized to total protein content in the corresponding wells and expressed as pmol/min/mg protein.

To calculate ECAR measurements, cells were washed and changed to assay medium lacking glucose. Basal ECAR were measured four times and plotted as a function of cells under the basal condition followed by the sequential addition of glucose (25 mM), oligomycin (1 μg/ml) and 2-deoxyglucose (25 mM), an inhibitor for the hexokinase. The rate of glycolysis was determined by the difference between the basal ECAR from the ECAR after the addition of glucose. The glycolytic reserve was determined by subtracting the ECAR following the addition of oligomycin from the ECAR following the addition of glucose.

2.8. Histology and electron microscopy

The hearts were collected at 8 months of age, fixed in 10% buffered formalin, and embedded in paraffin. Serial 5-μm heart sections from each group were stained with hematoxylin and eosin or Masson’s trichrome [17]. For electron microscopy, the left ventricles were dissected from hearts, and fixed in 2% EM-grade glutaraldehyde (Sigma), 2% PFA in 0.2 M sodium cacodylate (pH 7.4; Sigma) overnight at 4 °C, and post-fixed in 1% osmium tetroxide (EM Sciences) in 0.2 M sodium cacodylate (pH 7.4) for 2 h at 4 °C. Tissue was treated with propylene oxide and resin embedded (EMBID 812 kit, EM Sciences). The osmicated samples were then dehydrated through a series of graded ethanol solutions and then infiltrated with propylene oxide (EM Sciences). Subsequently, the tissues were infiltrated with Durcupan ANE Fluka Araldite (Sigma Chemical) and embedded in the same resin. After polymerization, 80-nm sections were cut using a Reichert Ultracut E Ultramicrotome (Leica Microsystems, Bannockburn, IL), and the grids were subsequently stained with uranyl acetate and lead citrate. The sections were imaged using a Hitachi transmission electron microscope equipped for digital image acquisition.

2.9. Statistical analysis

Unless otherwise stated, results were expressed as a mean ± standard deviation of the mean. In vitro studies were repeated a minimum of three times. One-way analysis of variance (ANOVA) followed by the Bonferroni post hoc test or the unpaired Student’s t-test was used to identify significant differences between groups. Statistical analysis was performed using Sigma-STAT software, version 3.5 (Systat Software Inc., San Jose, CA, USA). A P-value of less than 0.05 was considered significant.

3. Results

3.1. Generation of mice deficient in LPP3 in cardiac myocytes

Global deletion of Plpp3 results in embryonic lethality due to failure to develop an extraembryonic vasculature [5]. Furthermore, we have identified that even a tissue specific deficiency of endothelial-LPP3 exhibits embryonic lethality due to defective cardiovascular development [6] and inducible knockouts of LPP3 show enhanced inflammation and permeability [6,7]. To study the biological function of LPP3 in the heart, we generated cardiomyocyte specific Plpp3 knockout mice. For this purpose, we utilized Plpp3<sup>fl/fl</sup> mice with two loxP sites flanking exons 3 and 4 of the Plpp3 locus [18]. These mice were crossed with mice expressing Cre recombinase under the control of the cardiac-specific alpha-myosin heavy chain promoter (Myh6-Cre) [12] to generate Myh6-LPP3-deficient mice (Plpp3<sup>Δ</sup>) (Fig. 1A).

3.2. Analysis of LPP3 expression

Recombination in the Plpp3 locus was confirmed by PCR analysis (Fig. 1B). To provide biochemical evidence that LPP3 expression is deficient in the heart, we looked at mRNA expression of LPP3 in knockout mice heart tissue, which was confirmed to be negligible when compared to the Plpp3<sup>fl/fl</sup> mice (Fig. 1C). Immunoblot analysis of heart tissue was performed to determine LPP3 protein expression. As shown in Fig. 1D, LPP3 expression was negligible in the heart from Plpp3<sup>Δ</sup> mice, when compared to Plpp3<sup>fl/fl</sup> hearts. When we compare the contribution of LPP3 in cardiomyocytes over the other two isoforms of phospholipid phosphatases, namely, LPP1 and LPP2, the significantly reduced phosphatase activity in our Plpp3<sup>Δ</sup> mice suggest that LPP3 has a more prominent role in the heart (Fig. 1E).

3.3. Mice lacking LPP3 in the heart have shorter life spans due to decreased cardiac function

Unlike global Plpp3 knockout mice, Plpp3<sup>Δ</sup> are viable and fertile. All mice reached adulthood with no obvious phenotype. However, they had a decreased life span of ~8 months (Fig. 2A). 3-month-old Plpp3<sup>Δ</sup> mice showed higher heart rates (642 ± 21 bpm) compared to Plpp3<sup>fl/fl</sup> mice (580 ± 17 bpm; P < 0.01) although the blood pressure was similar in mice from both genotypes (96 ± 9 mmHg; n = 19 in Plpp3<sup>fl/fl</sup> as compared to 92 ± 7 mmHg; n = 19 in Plpp3<sup>Δ</sup>). After 7 months of age, mutant mice displayed signs of progressive heart failure. They had enlarged hearts indicating dilated cardiomyopathy (Fig. 2A). Cardiac tissue samples from 8-month-old mice were stained with hematoxylin and eosin staining (Fig. 2B) to compare the myocardium. Plpp3<sup>Δ</sup> hearts exhibited sarcomere disarray whereas Plpp3<sup>fl/fl</sup> hearts had no abnormalities. Masson’s trichrome stained Plpp3<sup>Δ</sup> hearts showed increased density of connective tissue collagen matrix deposition (Fig. 2C). Ultrastructural studies in Plpp3<sup>Δ</sup> heart tissue demonstrated myofilament destruction and absence of glycogen with distinct disruption of the intercalated discs. Mitochondria showed vacuole formation with prominent disruption of the cristae and rupture of the double membrane with deposition of an amorphous dense body (Fig. 2D).

Based on the evidence described above, we sought to determine the performance of the left ventricle in 8-month-old knockout mice using echocardiography. We observed a significant reduction in the fractional shortening as well as ejection fraction in mice lacking LPP3 in the heart, suggesting a decline in the left ventricular function (Fig. 3A). The heart weight/body weight (HW/BW) ratio and left ventricular (LV) mass index were also significantly elevated in Plpp3<sup>Δ</sup> compared to Plpp3<sup>fl/fl</sup> control mice (Fig. 3B). Plpp3<sup>Δ</sup> mice had longer ventricular effective refractory periods compared to their Plpp3<sup>fl/fl</sup> littermates (38.25 ± 1.181 vs 18.67 ± 0.6667). These mice also had a higher incidence of inducible VT with 1.050 ± 0.1652 s of VT compared to the controls (Fig. 3C). Natriuretic peptide A and B (Nppa and Nppb) are secreted by...
Fig. 4. LPP3 negatively regulates LPA signaling responses in neonatal cardiomyocytes. A) expression, immunoblot and activity assay showed the absence of LPP3 in Plpp3Δ cardiomyocytes (n = 4). B) Increase cell surface area is observed upon stimulation with LPA (1 μM) in Plpp3Δ cardiomyocytes with increased ANF positive cells (n = 4). B) and C) Plpp3Δ cardiomyocytes showed increased levels of extracellular signal-regulated kinase (ERK) activation upon stimulation with LPA (1 μM) at different time point intervals (n = 3). Where indicated, cells were infected with lentivirus expressing human (h) LPP3 or a catalytically inactive LPP3 variant. D) Plpp3Δ cardiomyocytes showed increased levels of Rho activation upon stimulation with LPA (1 μM) (n = 3). E) ERK activation was measured in Plpp3Δ and Plpp3Δ cardiomyocytes 5 min after treatment with 2.5 μmol/L of the nonhydrolyzable LPA analog 1-oleoyl-2-O-methyl-rac-glycerophosphothionate (OMPT) (n = 3). *P < 0.01 by 1-way ANOVA.
3.4. LPP3 negatively regulates LPA signaling responses in cardiomyocytes

Lipid phosphatase activity measured in LPP3 immunoprecipitates accounted for less than 5% phosphatase activity in Plpp3Δ cardiomyocytes confirming that LPP3 is the predominant isoform in the myocardium (Fig. 4A). Furthermore, direct measurement of lipids in intact cells to determine LPA phosphatase activity showed that exogenously applied C17-LPA was degraded 6-fold more slowly by Plpp3Δ than control cells (Fig. 4A). Treatment with LPA led to a significantly higher increase in cell surface area in the Plpp3Δ cardiomyocytes. The number of ANF (Atrial Natriuretic Factor) positive cells, a biomarker of cardiovascular disease, was also higher in Plpp3Δ cardiomyocytes (Fig. 4B). The lack of LPP3 in cardiomyocytes enhanced LPA-mediated phospho-ERK activation by increasing and prolonging ERK phosphorylation. In comparison to Plpp3Δ cardiomyocytes, Plpp3Δ cardiomyocytes demonstrated a robust increase in LPA-induced phospho-ERK activation that persisted for up to 30 min (P < 0.001; Fig. 4C). Additionally, Plpp3Δ cardiomyocytes responded to lower levels of LPA, with an ≈ 3-fold increase in ERK activation at 5 min in response to 1 μM LPA (P < 0.001; Fig. 4C). Expression of murine or human LPP3, but not a catalytically inactive LPP3 mutant, rescued the phenotype of Plpp3Δ cardiomyocytes by reducing phosphorylation of ERK in response to LPA (Fig. 4D). Rho activation in response to LPA was also enhanced in Plpp3Δ cardiomyocytes (P < 0.001) and was corrected by overexpression of either murine or human LPP3, but not a catalytically inactive mutant (Fig. 4E). If LPP3-deficient cells showed enhanced LPA-signaling due to a reduction in LPA degradation, then the Plpp3Δ cardiomyocytes should respond normally to a poorly hydrolyzable receptor-active LPA mimic, such as the ester-linked thiophosphate derivative (1-oleoyl-2-O-methyl-rac-glycerophosphothionate, OMPT). To emphasize the need for enzymatic catalytic function, we found that OMPT-stimulated ERK activation responses of Plpp3Δ and Plpp3Δ cardiomyocytes were similar (Fig. 4F).

3.5. LPP3 is required for cardiomyocyte mitochondrial respiration and function

Since the mitochondrial damage was observed, as shown in Fig. 2, we isolated mitochondria from the myocardium of the 8-month-old Plpp3Δ mice. These were used to determine the impact of LPP3 on mitochondrial bioenergetics. Mitochondria from Plpp3Δ hearts showed a significant decrease (P < 0.001; Fig. 5A and B) in the basal oxygen consumption rate, mitochondrial ATP production, maximal respiration and spare respiratory capacity when compared to the same parameters found in mitochondria from Plpp3Δ hearts. To further clarify the role of LPP3 in the myocardium, we used neonatal cardiomyocytes to determine the mitochondrial activity and superoxide levels. There also was a significant reduction in the basal oxygen consumption rate, mitochondrial ATP production, maximal respiration and spare respiratory capacity of neonatal Plpp3Δ cardiomyocytes (P < 0.001; Fig. 5C and D). We examined glycolysis in these neonatal cardiomyocytes by ECAR, and the opposite pattern to OCR was observed for glycolysis rates between Plpp3Δ and Plpp3Δ cardiomyocytes (Fig. 5E). The reverse relation of oxidative phosphorylation and glycolysis rates indicated changes in the metabolism for energy generation in Plpp3Δ and Plpp3Δ cardiomyocytes and is indicative of an early mitochondrial dysfunction in Plpp3Δ hearts. Then, we determined the free radical regulation of Plpp3Δ cardiomyocytes by measuring the superoxide anion using a fluorescent cholesterol analog, dihydroethidium. Increased basal superoxide production was observed in neonatal Plpp3Δ cardiomyocytes. When treated with LPA, Plpp3Δ cardiomyocytes showed higher superoxide levels as compared to LPA-treated Plpp3Δ cells. LPA-induced superoxide production was lowered by the addition of mitoTEMPO, a mitochondrial-specific superoxide scavenger. A similar reduction of superoxide was observed by the reintroduction of LPP3 expression (Fig. 5F). These findings point to the significance of LPP3 expression in mitochondrial function in response to cardiomyopathy, so we measured their levels in the failing Plpp3Δ hearts. As shown in Fig. 3D, an increase in the expression of these cardiomyocyte stress-response genes was observed. Together, these results suggest that LPP3 is essential for cardiac function. Since the role of LPP3 is dephosphorylation of LPA, we measured LPA levels in the plasma. The circulating plasma levels of LPA were increased ≈ 2-fold in the Plpp3Δ mice as compared to Plpp3Δ littermates (Fig. 3E).

Fig. 4. (continued)
oxidative phosphorylation as well as in the normal physiology of the myocardium in adult mice.

4. Discussion

LPP3 is a regulator of cell signaling because of its role in the dephosphorylation of LPA, which has been implicated in the many cardiovascular diseases [10,11,8]. To provide insight into the role of LPP3 in the cardiovascular system, we developed the heart specific Plpp3 knockout mice. The data obtained in Plpp3-Δ mice indicate that although lack of LPP3 in the cardiomyocytes allows for the normal development of the heart, it is critical for optimal functioning in adult mice. Several independent genome-wide association studies revealed a link between a frequently occurring polymorphism in the Plpp3 locus with an increased risk of coronary artery disease [19–21]. Our previous studies demonstrated that lack of LPP3 in endothelial and a subset of hematopoietic cells resulted in embryonic lethality with striking cardiovascular development defects [6]. Although the effects of LPP3 have been widely studied, little is known about LPA-mediated signaling pathways that are regulated by LPP3 in the myocardium.

In the current study, we have demonstrated that the absence of LPP3 in cardiomyocytes leads to progressive heart failure and a significantly shortened life span in mice (Fig. 3). Cardiac specific deletion of Plpp3 results in mice which survive and are fertile but more interestingly, their cardiac function and structure are normal at younger age, suggesting that either LPP3 expressed in the cardiomyocytes does not play an essential role in early cardiovascular development or the alpha myosin heavy chain – Cre/loxP system used in the generation of these mice allows LPP3 expression in the cardiomyocytes during early embryogenesis.

These mice have normal cardiac function and histology up to 3 months of age. Although these mice seem to have no cardiac functional abnormalities at a young age, it is possible that use of more invasive measurements along with increased cardiac workload may uncover underlying conditions. After 7 months of age, the lack of LPP3 in Plpp3-Δ mice resulted in a two-fold increase in the circulating LPA compared to its Plpp3Δ counterparts. Left ventricular (LV) function, as measured by the percent of fractional shortening (%FS) and ejection fraction (%EF), was prominently decreased in Plpp3-Δ mice. Also, cardiomyocyte disarray and sarcomere disruption were evident in the failing hearts that lacked LPP3. Furthermore, transmission electron micrograph studies revealed fragmentation and disorientation of myofibrils, distinct disruption of the intercalated discs, intermyofibrillar edema, rupture of cristae and double membrane with deposition of amorphous dense bodies in the failing myocardium of the Plpp3-Δ mice.

The use of neonatal cardiomyocytes allowed us to show that LPP3 regulates LPA-mediated phosphorylation of ERK, Rho activation, cardiomyocyte hypertrophy and genetic markers of cardiac stress such as atrial natriuretic factor (Nppa) and B-type natriuretic peptide (Nppb). Although LPP3 in cardiomyocytes regulates LPA-mediated phosphorylation of ERK, Rho activation, cardiomyocyte hypertrophy and genetic markers of cardiac stress such as ischemia and pathological hypertrophy [25]. Studies have shown simple glycerophospholipid LPA-mediated ROS production in cell culture models [26,27], however, its effect on mitochondrial bioenergetics in cardiomyocytes needs more research. Our real-time observation studies on mitochondrial oxidative phosphorylation status revealed mitochondrial dysfunction with increased production of superoxide (a normal byproduct of oxidative phosphorylation) that is formed at increased rates when the electron transport chain is defective) in the cardiomyocytes that lack LPP3. Oxidative stress was mitigated by the re-expression of LPP3. These findings indicate an important role for LPP3 in the prevention of oxidative stress caused by mitochondrial dysfunction. Our data add to the weight of the evidence that LPP3 regulates cardiomyocyte function. Although the lack of LPP3 clearly impairs LPA degradation and inactivation, additional non-LPA-dependent mechanisms of LPP3 action could also affect cardiomyocyte function. For example, LPP3 have non-enzymatic functions mediated by integrin binding or β-catenin signaling [5,28].

Emerging evidence supports a role for lysophospholipid mediators in the regulation of cardiac development and function [6,7,28]. Our findings provide functional evidence for a novel role of LPP3 mediated lipid metabolism in adult myocardium. Longer VERPs observed in Plpp3-Δ mice could mean that the action potentials are longer in these animals, which could then cause early and delayed afterdepolarizations leading to arrhythmias [29,30]. Infusion of LPA in rabbits increases ventricular arrhythmia and the proportion of non-phosphorylated connexin43, which may inhibit junction transmission [31]. Whether LPP3 regulates any of these responses is not known. Future studies should address these intriguing questions.

Fig. 5. Mitochondrial activities in Plpp3Δ mitochondria (A and B) and neonatal cardiomyocytes. (C and D). Oxygen consumption rate (OCR, pmol/min/µg protein) determined with XF24 analyzer oxidative phosphorylation activity. Extracellular acidification rate (ECAR) by XF24 analyzer for glycolysis activity (E). Superoxide radicals produced in the cardiomyocytes were analyzed using a dihydroethidium fluorescence probe (F). All values are mean ± SD (n = 5). *P < 0.05 as compared to control; †P < 0.05 as compared to LPA (1 µM) stimulated cells.
