(Received 28 November 2017; accepted 16 January 2018; published online 30 January 2018)

La atom reactions with 1-butene, 2-butene, and isobutene are carried out in a laser-vaporization molecular beam source. The three reactions yield the same La-hydrocarbon products from the dehydrogenation and carbon-carbon bond cleavage and coupling of the butenes. The dehydrogenated species La(C₄H₆) is the major product, which is characterized with mass-analyzed threshold ionization (MATI) spectroscopy and quantum chemical computations. The MATI spectrum of La(C₄H₆) produced from the La+1-butene reaction exhibits two band systems, whereas the MATI spectra produced from the La+2-butene and isobutene reactions display only a single band system. Each of these spectra shows a strong origin band and several vibrational progressions. The two band systems from the spectrum of the 1-butene reaction are assigned to the ionization of two isomers: La[C(CH₂)₃] (Iso A) and La(CH₂CHCHCH₂) (Iso B), and the single band system from the spectra of the 2-butene and isobutene reactions is attributed to Iso B and Iso A, respectively. The ground electronic states are ²A₁ (C₃v) for Iso A and ²A' (C₃v) for Iso B. The ionization of the doublet state of each isomer removes a La 6s-based electron and leads to the ¹A₁ ion of Iso A and the ¹A' ion of Iso B. The formation of both isomers consists of La addition to the C=C double bond, La insertion into two C(sp³)–H bonds, and H₂ elimination. In addition to these steps, the formation of Iso A from the La+1-butene reaction may involve the isomerization of 1-butene to isobutene prior to the C–H bond activation, whereas the formation of Iso B from the La+trans-2-butene reaction may include the trans- to cis-butene isomerization after the C–H bond activation. I. INTRODUCTION

Spectroscopy of transition metal-hydrocarbon radicals or ions formed in gas phase reactions has recently attracted considerable attention. Metal ion-hydrocarbon species are largely investigated by infrared or ultraviolet-visible photodissociation or photoelectron spectroscopy, 1–20 whereas metal atom-hydrocarbon radicals are mainly studied by resonant two-photon ionization and dispersed fluorescence, 21–24 Fourier transform microwave, 25 and mass-analyzed threshold ionization (MATI) spectroscopy. 25–33 Spectroscopic measurements probe the state specific energetics and structures of short-lived species, which are vital for gaining insight into reaction mechanisms and electronic and structural characteristics for efficient bond activation at metal centers. Such measurements can also be used to validate electronic structure calculations, where the computations are complicated by possibly multiple low-energy isomers of each metal-containing species and high-dense low-lying electronic states or spin-orbit levels of each isomer. On the other hand, spectroscopic measurements of transition metal-hydrocarbon radicals formed by the C–H or C–C bond activation of hydrocarbon compounds encounter substantial challenges because such radicals are produced with low number density. We have recently reported the MATI spectroscopy and formation of the metal-hydrocarbon radicals produced by the lanthanide-mediated C–C and C–H bond activation of several small alkenes and alkynes. 26–35 Our studies have demonstrated that the combination of the MATI spectroscopic measurements with theoretical computations is a powerful approach to investigate transient metal-hydrocarbon species.

Butene (C₄H₆) has three common structural isomers: 1-butene (CH₂=CHCH₂CH₃), 2-butene (CH₃CH=CHCH₃), and 2-methylpropane or isobutene (CH₃C(CH₃)₂). Their reactions with metal ions have been investigated with mass-spectrometry-based techniques. 34–45 For 1- and 2-butenes, loss of H₂ is the exclusive or predominate reaction with M⁺ = Sc⁺, Fe⁺, Co⁺, Ni⁺, Ln⁺, and Pt⁺; Ln = lanthanide and leads to presumably butadiene complexes M⁺(C₄H₆). 34,36,38,39,41,44 This contrasts the behavior of isobutene, which formed only sequential adducts with Fe⁺ but is dehydrogenated by Co⁺, Ni⁺, and Sc⁺ to form M⁺(C₄H₆). 38,39 Collision-induced dissociation, ion-molecule reactions, and deuterium exchanges indicated that the M⁺(C₄H₆) ions generated from the isobutene reactions were likely M⁺(butadiene) with M⁺ = Co⁺ or Ni⁺ at 38 but M⁺(trimethylenemethane) with M⁺ = Sc⁺. 39 Dehydrogenation of the butenes has also been observed by various transition metal atoms. 35,46–48 For example, Y(C₄H₆)+H₂ was observed using crossed molecular beams as the predominant process for the Y reactions with 1-butene, 2-butene, and isobutene at collision energies of 11.0 and 26.6 kcal mol⁻¹.

although Y(H$_2$)+C$_4$H$_8$ was also detected as a significant channel for Y+1- and 2-butenes at the 26.6 kcal mol$^{-1}$ collision energy.$^{49}$

In this article, we report the spectroscopic characterization of La(C$_4$H$_8$) formed by La reactions with the three isomers of the butenes using MATI spectroscopy. The motivation was to determine spectroscopically the structures of the dehydrogenated species and to understand how a La atom activates the C—H bond and removes H$_2$ from the butenes. To our knowledge, this is the first vibronic spectroscopic measurement of metal radicals formed by the C—H bond activation of the butenes.

II. EXPERIMENTAL AND COMPUTATIONAL METHODS

A. Experimental

The metal-cluster beam instrument used in this work consists of reaction and spectroscopy vacuum chambers and was described in a previous publication.$^{50}$ Metal-hydrocarbon reactions were carried out in a laser-ablation metal cluster beam source. Each of the gaseous butenes (1-buten, 2-buten, and isobutene: $\geq$99%, Aldrich) was seeded in a He (99.998%, Scott Gross) carrier gas with a butene: He molar ratio of $\sim$10$^{-5}$-10$^{-7}$ in a stainless steel mixing cylinder. La atoms were generated by pulsed-laser (Nd:YAG, Continuum Minilite II, 532 nm, $\sim$1.0 mJ/pulse) ablation of a La rod (99.9%, Alfa Aesar) in the presence of the butene/carrier gas mixture (40 psi) delivered by a home-made piezoelectric pulsed valve. The metal atoms and gas mixture entered into a collision tube (2 mm diameter and 2 cm length), were then expanded into the reaction chamber, collimated by a cone-shaped skimmer (2 mm inner diameter), and passed through a pair of deflection plates. Ionic species in the molecular beam that was formed by laser ablation were removed by an electric field (100 V cm$^{-1}$) applied on the deflection plates, and neutral products were identified by photoionization TOF mass spectrometry.

Prior to the MATI measurements, photoionization efficiency spectra of La(C$_4$H$_8$) were recorded to locate an approximate ionization threshold to guide MATI scans. In the MATI experiment, La(C$_4$H$_8$) was excited to high-lying Rydberg states in a single-photon process and ionized by a delayed pulsed electric field. The excitation laser was the frequency-doubled output of a tunable dye laser (Lumonics HD-500), pumped by the third harmonic output (355 nm) of a Nd:YAG laser (Continuum Surelite II). The laser beam was collinear and counter propagating with the molecular beam. The ionization pulsed field (320 V cm$^{-1}$), which was also used for accelerating ions into the field free region, was generated by two high voltage pulse generators (DEI, PVX-4140) and delayed by $\sim$20 $\mu$s from the laser pulse by a delayed pulsed generator (SRS, DG645). A small dc field (6.0 V cm$^{-1}$) from another power supply (GW INSTEK, GPS-30300) was used to separate the ions produced by direct photoionization from the MATI ions generated by the delayed field ionization. The MATI ion signal was obtained by scanning the tunable dye laser, detected by a dual microchannel plate detector, amplified by a preamplifier (SRS, SR445), visualized by a digital oscilloscope (Tektronix TDS 3012), and stored in a laboratory computer. Laser wavelengths were calibrated against titanium atomic transitions in the MATI spectral region, and the calibration was done after recording the MATI spectra.$^{51}$ The Stark shift on the adiabatic ionization energy ($\Delta$AIE) induced by the dc field ($E_d$) was calculated using the relation of $\Delta$AIE = $6.1E_d^{1/2}$, where $E_d$ is in V cm$^{-1}$ and AIE is in cm$^{-1}$.52

B. Computational

Density functional theory (DFT) method with the Becke’s three-parameter hybrid functional with the correlation functional of Lee, Yang, and Parr (B3LYP) was used to calculate the equilibrium geometries and vibrational frequencies of various isomers of La(C$_4$H$_8$) and the free ligands. The basis sets used in these calculations were 6-311+G(d,p) for C and H and the Stuttgart/Dresden (SDD) effective-core-potential basis set with 28 electron core for La. We have extensively used the DFT/B3LYP method and found that this method generally produced adequate results for spectral and structural assignments of organometallic radicals.26-28,30-32,53 No symmetry restrictions were imposed in initial geometry optimizations, but appropriate point groups were used in subsequent optimizations to help identify electronic symmetries. For each optimized stationary point, a vibrational analysis was performed to identify the nature of the stationary point (minimum or saddle point). In predicting reaction pathways, minima connected by a transition state were confirmed by intrinsic reaction coordinate calculations. To refine the energies of the lowest doublet and singlet states, single-point energy calculations were carried out with the coupled cluster with single, double, and perturbative triple [CCSD(T)] excitations method. These calculations involve the third-order Douglas-Kroll-Hess scalar relativistic correction and at the DFT/B3LYP optimized geometries. Basis sets used in the CCSD(T) calculations were aug-cc-pVTZ-DK$^{54,55}$ for C and H and cc-pVTZ-DK$^{36}$ for La. The DFT calculations were performed with Gaussian 09 software package,$^{57}$ whereas the CCSD(T) calculations were carried out with MOLPRO 2010.1$^{58}$

To compare with the experimental MATI spectra, multidimensional Franck-Condon (FC) factors were calculated from the equilibrium geometries, harmonic vibrational frequencies, and normal coordinates of the neutral and ionized complexes.$^{59}$ In these calculations, the recursion relations from the work of Doktorov et al.$^{60}$ were employed, and the Duschinsky effect$^{61}$ was considered to account for a possible axis rotation from the neutral complex to the cation. Spectral simulations were obtained using the experimental line width and Lorentzian line shape. Transitions from excited vibrational levels of the neutral complex were considered by assuming thermal excitation at specific temperatures.

III. RESULTS AND DISCUSSION

A. TOF mass spectra and La-hydrocarbon species

Figure 1 displays the TOF mass spectra of the La reactions with 1-buten, 2-buten, and isobutene recorded with 240-250 nm photoionization. The mass spectra from all the butene reactions are essentially the same and show a predominant product La(C$_4$H$_8$) and several other metal-hydrocarbon species. La(C$_4$H$_8$) is formed by the loss of H$_2$ from C$_4$H$_8$, La(C$_3$H$_{14}$),...
which is a minor species in the 1- and 2-butene reactions but becomes more significant in the isobutene reaction, is formed by a secondary reaction, possibly La(C4H6)+C4H8. Two other minor species are La(C2H2) and LaO(C4H8), with the smaller species being formed by the C=C cleavage and the larger one by the addition of LaO with a butene molecule. The observation of the adduct LaO(C4H8) suggests that LaO is less reactive than La. LaO could be formed by La reactions with oxygen that is present in the carrier gas as an impurity or by laser vaporization of La oxide impurity in the La rod.26–28,30–33 The observation of the predominating H2 loss is similar to previous studies on butene reactions with other metal atoms or ions.34–48

B. MATI spectra and isomers of La(C4H6)

MATI spectra of La(C4H6) formed by the La reactions with 1-butene, 2-butene, and isobutene are different as shown in Fig. 2. The spectrum of La(C4H6) from the La+1-butene reaction [Fig. 2(a)] displays two band systems, with the stronger band system originating at 39 418 (5) cm⁻¹ and the weaker one originating at 41 264 (5) cm⁻¹. The 39 418 cm⁻¹ band system consists of a 396 cm⁻¹ progression with up to three vibrational quanta, two bands at 318 and 470 cm⁻¹, and several other weaker bands marked with ‘∗1, ∗2, #1, and #2’ at the higher energy side of the origin band. The ‘∗1 and ∗2’ bands are the combination bands of the 318 cm⁻¹ transition with the first and second quanta of the 396 cm⁻¹ progression, whereas the ‘#1 and #2’ bands are the combination bands of the 470 cm⁻¹ transition with the first and second quanta of the 396 cm⁻¹ progression, respectively. At the lower energy side, the 39 418 cm⁻¹ band system shows two weak bands at 289 and 374 cm⁻¹, which are due to transitions from vibrationally excited levels of the neutral species. The 41 264 cm⁻¹ band system is much weaker but clearly displays a 353 cm⁻¹ transition at the higher energy side and a 326 cm⁻¹ transition at the lower energy side of the origin band. The spectrum of La(C4H6) formed by the La+2-butene reaction [Fig. 2(b)] is essentially the same as the 39 418 cm⁻¹ band system of the species formed by La+1-butene, though the signal-to-noise ratio is lower.

Because of the weaker signals, some of the weak bands are not as well resolved as those in the spectrum from the La+1-butene reaction. On the other hand, the spectrum of La(C4H6) produced by La+isobutene has a much higher signal-to-noise ratio [Fig. 2(c)]. It not only reproduces the three bands of the 41 264 cm⁻¹ band system of the species formed by the 1-butene reaction but also shows at the higher energy side of the 41 264 cm⁻¹ origin band a 240 cm⁻¹ progression with up to two quanta, two more quanta of the 353 cm⁻¹ progression, and two additional bands at 900 and 958 cm⁻¹.

Figure 3 displays the structures of the doublet ground states of the three low-energy isomers of La(C4H6),32 along with the structures of the singlet ground states of the butene

![FIG. 1. TOF Mass spectra of La+1-butene (a), La+2-butene (b), and La+isobutene reactions recorded with 240-250 nm photoionization.](image)

![FIG. 2. MATI spectra of La(C4H6) produced from La reactions with 1-butene [(a), black], 2-butene [(b), dark blue], and isobutene [(c), dark red] and simulations of the 1A₁ ← 2A₁ transition of La[C(CH₂)₃] (C₃v) (Iso A) [(d), blue] and the 1A’ ← 2A’ transition of La(CH₂CHCH₂) (C₃) (Iso B) [(e), red] at 300 K.](image)

![FIG. 3. Structures of the ground states of butene [(a)–(d)] and La(C4H₆) [(e)–(g)] isomers. Relative energies of these species are listed in Table I.](image)
isomers (C₄H₈). Table I lists relative electronic energies including vibrational zero point corrections of various spin states of the La(C₄H₈) isomers predicted by the DFT/B3LYP calculations and the doublet ground states and singlet ion states of those isomers predicted by the CCSD(T) single-point energy calculations. The relative energies of the butenes follow the order of isobutene < 2-butenes < 1-butene. The two conformers of cis- and trans-2-butene are close in energies, with the trans form being slightly more stable. The three isomers of La(C₄H₈) are trimethyleneemethanlanthanum [La(C(CH₂)₃)] (Iso A), 1-lanthanacyclopent-3-ene [La(C₂H(CH₂)₂), Iso B], and (trans-butadiene)lanthanum [La(trans-C₄H₇), Iso C]. The most stable isomer is predicted to be Iso A, followed by Iso B and Iso C. For each isomer, the ground state of the neutral species is a doublet state, followed by a quartet state; the lowest energy state of the corresponding ion is a singlet state, followed by a triplet state. At the DFT/B3LYP computational level, the energy differences between the quartet and doublet neutrals are predicted to be 2.03 eV (1 eV = 8065 cm⁻¹) for Iso A, 1.26 eV for Iso B, and 0.92 eV for Iso C. The energy differences between the triple and singlet ions are 1.60 eV for Iso A, 1.09 eV for Iso B, and 0.60 eV for Iso C. The lower spin states in the neutral and ion states are more stable due to the stronger metal-ligand binding, as evidenced by the shorter La—C distances (Table S1 of the supplementary material). Among the neutral doublet states of the three isomers, the 2A¹ state of Iso A (C₃v) has the lowest energy, the 2A¹ state of Iso B (C₄v) is predicted at ~0.01 eV by B3LYP and 0.13 eV by CCSD(T), and the 2A² state of Iso C (C₂v) is at 0.46 and 0.53 eV by the two computational methods.

The 39 418 cm⁻¹ band system of La(C₄H₆) from the 1-butene reaction and the spectrum of La(C₄H₆) from the 2-butene reaction are assigned to the 1A' ← 2A¹ transition of Iso B. The 41 264 cm⁻¹ band system of La(C₄H₆) from the 1-butene reaction and the spectrum of La(C₄H₆) from the isobutene reaction are attributed to the 1A¹ ← 2A¹ transition of Iso A. These assignments are supported by the agreement between the measurements and calculations, as demonstrated in Table II and Fig. 2. Table II summarizes the measured and calculated AIEs and vibrational frequencies. Figure 2 compares the simulated vibronic spectrum of the 1A' ← 2A¹ transition of Iso B [Fig. 2(e)] to the 76 211 cm⁻¹ band system from the 1- and 2-butene reactions [Figs. 2(a) and 2(b)] and the simulated vibronic spectrum of the 1A¹ ← 2A¹ transition of Iso A [Fig. 2(d)] to the 41 264 cm⁻¹ band system from the 1-butene and isobutene reactions [Figs. 2(a) and 2(c)]. The origin bands in the simulations are aligned with those in the experimental spectra, but the computed vibrational frequencies are uncaled in order to directly compare with the experimental spectrum. For the 39 418 cm⁻¹ band system in Figs. 2(a) and 2(b), the 470, 396, and 318 cm⁻¹ vibronic bands are assigned to excitations of a symmetric La-ligand stretch coupled with a terminal CH₂ rock (ν₁₁ +, a'), a second symmetric La-ligand stretch mixed with another terminal CH₂ rock (ν₁₂ +, a'), and a symmetric C—H bend of the middle HCC=CH group (ν₁₃ +, a') in the 1A' transition of Iso A.

Table II. Diabatic ionization energies (AIEs, cm⁻¹) and vibrational frequencies (cm⁻¹) of La[C(CH₂)₃] (Iso A) and La(C₂H(CH₂)₂) (Iso B) from MATI spectroscopy and theoretical calculations. ν₀ and ν₀'' are vibrational modes in the neutral and ionic states.

ion state of Iso B; the 374 and 289 cm\(^{-1}\) vibronic bands to the second La-ligand stretch/CH\(_2\) rock (\(v_{12}, a'\)) and C–H bend (\(v_{13}, a'\)) in the \(^2\text{A}^\text{a}\) state of the same isomer. The main difference between the two La-ligand stretch/CH\(_2\) rock modes is the opposite directions of the CH\(_2\) rocking motions. For the 41 264 cm\(^{-1}\) band system in Figs. 2(a) and 2(c), the \(^1\text{A}_1 ← ^2\text{A}_1\) simulation of Iso A reproduces the experimental 353 cm\(^{-1}\) vibronic band and the 326 cm\(^{-1}\) hot band. The 353/326 cm\(^{-1}\) bands are assigned to the symmetric La-ligand stretch excitations (\(v_5/v_6, a_1\)) of the \(^1\text{A}_1\) ion/\(^2\text{A}_1\) neutral states. The simulation also reproduces the second and third quanta of the 353 cm\(^{-1}\) progression and the weak 900 and 958 cm\(^{-1}\) transitions above the origin band in the spectrum of Fig. 2(c). The 900 and 958 cm\(^{-1}\) vibronic bands are assigned to the CH\(_2\) wag (\(v_{14}, a_1\)) and CH(CH\(_2\)) deformation (\(v_{32}, a_1\)) of the ion, respectively. However, the weak 240 cm\(^{-1}\) progression in Fig. 2(c) is not present in the simulation. This progression was previously attributed to excitations of a degenerate asymmetric La-ligand stretch (\(v_{18}, e\)) of La(C\(_2\)H\(_6\)) formed by the La reaction with propene, and the activity of the degenerate mode could be due to the Herzberg-Teller effect.\(^{32}\)

Other transitions of Iso A and B can be excluded from the observed MATI spectra. The 0–0 energies of the triplet ← doublet transitions of Iso A and B are predicted to be 54 731 and 49 039 cm\(^{-1}\), respectively, which are much higher than the energies of the experimental origin bands at 39 418 or 41 264 cm\(^{-1}\). Although the 0–0 energies of the triplet ← quartet transitions of the two isomers (38 367 cm\(^{-1}\) for Iso A and 38 807 cm\(^{-1}\) for Iso B) are not much different from the experimental 39 418 cm\(^{-1}\) origin band, the neutral quartet states are excited states at relatively high energies (2.03 eV for Iso A and 1.26 eV for Iso B) so that they are unlikely survived under the supersonic expansion conditions. Similarly, Iso C is not a candidate for the observed spectra because it is in significantly higher energy than the doublet states of either Iso A or B. Furthermore, simulations of the triplet ← doublet or triplet ← quartet transitions do not match the experimental observations.

The C(CH\(_2\))\(_3\) fragment in Iso A is a trimethylenemethane diradical, where the \(\pi\) system consists of four \(\pi\) electrons delocalized over four \(\pi\)-type molecular orbitals, two of which are degenerate.\(^{62}\) In the \(^2\text{A}_1\) state of Iso A (C\(_{2}v\)), C(CH\(_2\))\(_3\) has three equal C–C bonds (Table S1 of the supplementary material) and corresponds to the structure of the triplet ground state with two unpaired electrons in the degenerate \(\pi\) orbitals.\(^{62}\) The CH\(_2\)CHCHCH\(_2\) moeity in the \(^2\text{A}^\text{a}\) state of Iso B (C\(_{2}v\)) is a cis-1,3-butadiene neutral molecule rather than a radical. Thus, La does not undergo a two-electron transfer in the \(^4\text{A}^\text{a}\) state of either Iso A or Iso B, and the HOMOs of the quartet excited states of the two isomers have a La 5d character.

C. Formation of the two isomers of La(C\(_4\)H\(_6\))

Previously, we observed La(C\(_4\)H\(_6\)) formed by La atom reactions with ethylene,\(^{28}\) propene,\(^{32}\) and 1,3-butadienes.\(^{30}\) Iso A was identified from the La+propene reaction, which involves the C–C bond cleavage of propene in the primary reaction and the C–C coupling and dehydrogenation in the secondary reaction. Iso B was detected from the C–C bond coupling of ethylene, the association of 1,3-butadiene, and the C–C cleavage and coupling of propene. The formation of the two isomers of La(C\(_4\)H\(_6\)) by the La reactions with the butenes is different from those of the above reactions and is discussed below. Figures 4–7 illustrate the DFT/B3LYP computed stationary points for the formation of the two isomers from the H\(_2\) elimination of 1-butene, 2-butene, and isobutene, respectively. These stationary points include reactants, intermediates (IMn), transition states (TSn), and products in their doublet spin states. Energies of the stationary points are reported in Tables S2–S4 of the supplementary material. We consider the concerted H\(_2\) elimination because previous studies have shown that stepwise dehydrogenation paths are less favorable for the metal atom-mediated dehydrogenation of small alkenes and alkynes.\(^{26,28,30–32,63–69}\)

1. Formation of Iso A and Iso B by La reaction with 1-butene

The formation of Iso B from the La+1-butene reaction consists of La addition to the C=C double bond, La insertion into the C(CH\(_2\))\(_3\) fragment in the \(^4\text{A}^\text{a}\) state of Iso A (C\(_{2}v\)) has one longer C–C bond and two shorter ones (Table S1) and corresponds to the structure of a singlet excited state with two \(\pi\) electrons anti-parallel in the degenerate orbital. The CH\(_2\)CHCHCH\(_2\) moiety in the \(^4\text{A}^\text{a}\) state of Iso B (C\(_{2}v\)) is a cis-1,3-butadiene neutral molecule rather than a radical. Thus, La does not undergo a two-electron transfer in the \(^4\text{A}^\text{a}\) state of either Iso A or Iso B, and the HOMOs of the quartet excited states of the two isomers have a La 5d character.
to C(sp^3)−H bonds, and H₂ elimination. Figure 4 and Table S2 of the supplementary material present the stationary points and their energies along the reaction coordinates. The reaction begins with La atom addition to the C=C bond to form a π complex [La(CH₂CHCH₂CH₃), IM1] at 32.5 kcal mol⁻¹ below the reactants. Upon the La addition, the C=C double bond of 1-butene is elongated by 0.17 Å (from 1.331 Å to 1.505 Å) due to the cleavage of the π bond between the carbon atoms. The change from the C=C to C−C bond is also evidenced by the bending of the H atoms in the ethenyl group of the ligand. A molecular orbital analysis reveals that the unpaired π electron on each of the two ethenyl carbon atoms is paired with a La 5d electron to form a La−π bond. Thus, the resultant π complex can be considered 2-ethyl-1-

lanthanacyclopropane. The exothermic energy from the La addition to 1-butene (32.5 kcal mol⁻¹) is similar to those from La additions to ethylene (32.4 kcal mol⁻¹) and propene (29.7 kcal mol⁻¹) but significantly lower than those from La additions to propyne (52.3 kcal mol⁻¹) and 1- and 2-butynes (52.4 and 51.1 kcal mol⁻¹). The second step (IM1–IM3) is the activation of a C(sp³)−H bond of the CH₂ group in the β position. The β-carbon is defined as the carbon atom that is connected to the La-bonded α-carbon in the initially formed π complex (IM1). The C(sp³)−H bond activation involves the rotation of the Cₐ−Cₖ bond via TS1 to convert the trans-conformation of the ligand in IM1 to a cis-conformation in IM2, which is followed by the elongation of a Cₖ−H bond via TS2 to form IM3. In IM3, the La−Cₐ σ bonds are weaker than those in IM2 and a Cₖ−H bond is broken; concurrently, the Cₐ−Cₖ bond becomes almost a double bond and a La−H bond is formed. The third step (IM3–IM5) is the activation of a C(sp³)−H bond of the terminal CH₃ group in the γ position that is next to the β-carbon. This is accomplished by the rotation of the La−H bond in IM3 to form IM4 and the insertion of La into the methyl C(sp³)−H bond to form IM5. As a result, the C(sp³)−H bond is cleaved, and additional La−H and La−C(sp³) bonds are formed. Either of the two La−H bonds in IM5 (2.515 and 2.585 Å) is weaker than the La−H bond in IM4 (2.093 Å), and the La-bonded H−H distance (0.768 Å) is close to the equilibrium H−H bond length (0.774 Å) in a free H₂ molecule. The final step is the concerted H₂ elimination from IM5 to form ISO B. The whole process La+1-butene → ISO B is exothermic by 36.2 kcal mol⁻¹ and has no overall energy barrier. Along the reaction coordinates, the C(sp³)−H bond activation is preferred because it is weaker than a C(sp³)−H bond, C−C or La−H bond rotations have lower barriers (TS1 and TS3) than metal insertions into C−H bonds (TS2 and TS4), and the H₂ elimination (IM5–ISO B) is basically barrierless. Because the energy barriers (TS1–TS4) are considerably lower than the energy of the reactants, all intermediates (IM1–IM5) have tendency to convert to the product (ISO B). This may explain why no intermediates were observed in our experiments even though the two inserted species (IM3 and IM4)

are more stable than the product. This observation is similar to previous studies of La reactions with other small unsaturated hydrocarbons, except for propene where a La-inserted species was identified.

The formation of Iso A is more complicated due to the carbon skeleton rearrangement that involves both C–C bond cleavage and coupling prior to H2 elimination (Fig. 5 and Table S2 of the supplementary material). The first step is the same as that in the formation of Iso B, which is the La addition to form an IM1 π complex. The second step is the Cβ–Cγ cleavage (IM1–IM8). This step consists of the Cα–Cβ bond rotation to bring the ligand to a cis-conformation to form IM6, the La insertion into the Cβ–Cγ bond to form IM7, and the rotation of the La–CH3 bond to form IM8. IM6 is similar to IM2, except that the Cγ atom in the methyl group is near the La atom. Although both IM7 and IM8 may be considered methyl(η3-allyl)lanthanum [(CH3)La(CH2CHCH2)], the La–CH3 bonds in the two minima are in almost opposite orientations and the CH3 group in IM8 is closer to the Cα atom. The third step is the C–C coupling to form 3-methyl-1-lanthanacyclobutane [La(CH2CH(CH3)CH2)], where the metal-allaclyl and the methyl group are in a chair (IM9) or a boat conformation (IM10). The final step is the H2 elimination from two C(sp3)–H bonds to form Iso A (IM10-Iso A). As in the case of the Iso B formation, the dehydrogenation involves the La insertion into the Cα(sp3)–H bond to form an inserted species (IM11), a second insertion into a C(sp3)–H bond of the methyl group to form a dihydrogen complex (IM12), and a concerted H2 elimination from IM12. The La+1-butene → Iso A reaction is exothermic by 36.5 kcal mol⁻¹ and has no overall energy barriers. The C–C cleavage and coupling in the formation of Iso A require more energies (TS6 at 18.6 kcal mol⁻¹ and TS8 at 40.7 kcal mol⁻¹) than the C–H bond activation in the Iso B formation (TS2 at 5.9 kcal mol⁻¹ and TS4 at 16.4 kcal mol⁻¹). Because of the higher energy barriers, the formation of Iso A is kinetically less favorable than the formation of Iso B. The less favorable kinetics may explain the weaker spectral signal of Iso A even though it is predicted to be slightly more stable than Iso B.

2. Formation of Iso B by La reaction with 2-butene

Because 2-butene used in our experiment is a mixture of the trans and cis conformers, we consider reaction paths for both La+trans-2-butene → Iso B (solid blue lines) and La+cis-2-butene → Iso B (solid red lines) (Fig. 6 and Table S3 of the supplementary material). Similar to La+1-butene → Iso B, the La-mediated dehydrogenation processes of trans- and cis-2-butenes include the initial formation of a π complex (IM 13 or IM18), the activation of two C(sp3)–H bonds in two methyl groups (IM13-IM16 or IM18-IM5), and the concerted H2 elimination from a dihydrogen complex (IM16-IM17 or IM15-IsoB). Both reactions are thermodynamically favorable with exothermic energies ~32 kcal mol⁻¹. Yet, differences are noted between the trans- and cis-2-butene reactions. First, after the H2 elimination the trans-2-butene reaction undergoes the isomerization of the CH3CHCH3 fragment from the trans form in IM17 to the cis form in Iso B and the shift of La binding positions from the middle to the terminal two carbons. IM17, which is the same as Iso C, is about 10 kcal mol⁻¹ higher than Iso B. Iso B could also be formed from isomerization followed by dehydrogenation. But this process is expected to be less favorable, as demonstrated by the La-mediated 1,3-butadiene dehydrogenation where H2 elimination was found to occur before the trans to cis isomerization. Second, the cis-2-butene reaction shares two same intermediates (IM4 and IM5) as those of the 1-butene reaction along the coordinates of the Iso B formation. Finally, the energy barriers of the cis-2-butene reaction are lower than those of the trans-2-butene reaction, suggesting that the former is kinetically more favorable than the latter.

3. Formation of Iso A by La reaction with isobutene

The La-mediated dehydrogenation of isobutene produces only Iso A. The predicted pathway for the formation of Iso A from the isobutene reaction also consists of the formation of a π complex, La insertion into to C(sp3)–H bonds, and H2 elimination (Fig. 7 and Table S4 of the supplementary material). These steps are similar to those for the formation of Iso B by the 1-butene or cis-2-butene reaction. The reaction begins with the formation of the π complex at ~29.4 kcal mol⁻¹ (IM20) and proceeds with the La insertion into one of the C(sp3)–H bonds in a CH3 group to form an inserted species (IM21). Prior to the second La insertion into a C(sp3)–H bond in the other CH3 group, the La–H bond in IM21 rotates to a position where the metal-bonded H atom is in the proximity of the methyl group and to form a new inserted species (IM11). From this point, the reaction proceeds with the same steps as those of the La+1-butene → Iso A reaction (IM11-Iso A). The overall reaction is barrierless and exothermic by 32.7 kcal mol⁻¹.

IV. CONCLUSIONS

We have reported the MATI spectra and formation of La(C4H6)2 formed by the La-mediated dehydrogenation of 1-butene, 2-butene, and isobutene. The spectra of La(C4H6)2 formed in the 1-butene reaction exhibit two band systems, which are assigned to the ionization of the La[CH2(CH3)3] and La(CH2CHCHCH2) isomers. The spectra of La(C4H6)2 formed in the 2-butene and isobutene reactions both display a single band system, and the former is attributed to La(CH2CHCHCH2) and the latter is attributed to La[CH2(CH3)3]. The MATI measurements yield AIEs and metal-ligand stretching and ligand-based bending frequencies for the two isomers. The ground state of each isomer is a doublet state with a La-based 6s electron, ionization has a small effect on the geometry of the neutral state. Quantum chemical calculations suggest that formations of the two isomers consist of the La addition to the C=C triple bond, La insertion into C(sp3)–H bonds, and concerted dehydrogenation. The C–H bond activation takes places after the C–C bond cleavage and coupling in the reaction of La+1-butene to form La[CH2(CH3)3], while it occurs before the trans to cis isomerization in the La+trans-2-butene reaction to form La(CH2CHCHCH2).
SUPPLEMENTARY MATERIAL

See supplementary material for the geometries of the La(C₆H₅)₃ isomers and the energies of the stationary points along the reaction coordinates for the formation of La[Si(CH₃)₂]₃ and La(CHₓCHCHₓCH₃)₂ formed by La atom reactions with 1-butene, 2-butene, and isobutene.
