ABSTRACT OF THESIS

DESIGN ENHANCEMENT AND INTEGRATION OF A PROCESSOR-MEMORY INTERCONNECT NETWORK INTO A SINGLE-CHIP MULTIPROCESSOR ARCHITECTURE

This thesis involves modeling, design, Hardware Description Language (HDL) design capture, synthesis, implementation and HDL virtual prototype simulation validation of an interconnect network for a Hybrid Data/Command Driven Computer Architecture (HDCA) system. The HDCA is a single-chip shared memory multiprocessor architecture system. Various candidate processor-memory interconnect topologies that may meet the requirements of the HDCA system are studied and evaluated related to utilization within the HDCA system. It is determined that the Crossbar network topology best meets the HDCA system requirements and it is therefore used as the processor-memory interconnect network of the HDCA system. The design capture, synthesis, implementation and HDL simulation is done in VHDL using XILINX ISE 6.2.3i and ModelSim 5.7g CAD softwares. The design is validated by individually testing against some possible test cases and then integrated into the HDCA system and validated against two different applications. The inclusion of crossbar switch in the HDCA architecture involved major modifications to the HDCA system and some minor changes in the design of the switch. Virtual Prototype testing of the HDCA executing applications when utilizing crossbar interconnect revealed proper functioning of the interconnect and HDCA. Inclusion of the interconnect into the HDCA now allows it to implement “dynamic node level reconfigurability” and “multiple forking” functionality.

ACKNOWLEDGEMENTS

I would like to thank my advisor and guide Dr. Heath for his constructive advice and support which helped me complete my thesis in a timely manner.

I would also like to thank my committee members Dr. Dietz and Dr. Dieter for their valuable support. Each individual provided insights that guided and challenged my thinking, substantially improving the finished product.

In addition to the technical and instrumental assistance above, I received equally important assistance from my family and friends.

Chapter One

Introduction

1.1 Background and Positioning of Research

Most parallel/distributed architectures require some type of interconnection network to link the various elements of the computer system. Anyone designing a parallel or distributed architecture computer system encounters a major obstacle; the Interconnection Network problem. A multiple processor system consists of two or more processors connected to each other in a manner that allows them to share the simultaneous execution of a given computational task. Interconnection networks should be capable of providing rapid data transfer among processors; memories etc.

There are a number of styles of communication for multiprocessor networks. These can be broadly classified according to the communication model as multiple processors (single address space/shared memory) versus multiple computers (multiple address/distributed memory). They can be classified according to the physical connection used as bus based versus network based multiple processors. The organization and performance of a multiple processor system is greatly influenced by the interconnection network used to connect them. A single shared bus network or a crossbar switch can be used as an interconnection network. While the first technique represents a simple, easy to expand topology; it is however limited in performance since it does not allow more than one processor/memory transfer at any given time. The crossbar provides full processor/memory distinct connections however it can be expensive. Multistage interconnection networks sometimes strike a balance between the limitation of a single shared bus network system and expense of crossbar switch system. The cost of multistage interconnection network can be considerably less as compared to the crossbar, especially for large numbers of processor/memories. Crossbar interconnect, though are cost and complexity competitive with other types of interconnects when within a certain size range, as will be later addressed. Another way to connect the multiple processors to multiple memories is to use multiple bus system. It can also be suggested as a compromise between shared bus system and crossbar switch.
This thesis is primarily a study of various kinds of interconnect networks which may meet the requirements of the Hybrid Data/Command Driven Architecture (HDCA) multiprocessor system [16,17,7] shown in Figure 1.1. It then involves enhancement of a design developed in [6]. The design is described in Vhsic Hardware Description Language (VHDL) for an interconnect network suitable for integration into the HDCA system.

The HDCA is a multiprocessor shared memory architecture. It is a hybrid data flow machine since it uses data flow concepts to migrate data from one process to another yet uses a program counter in the actual execution of processes on processors. It utilizes advantages of both Von-Neumann and data flow type architectures [16,17]. The shared memory is organized as a single memory divided into blocks as shown in the Figure 1.1 and is explained in detail in Chapter 3. The interconnect network to be designed should be able to connect requesting processors on one side of the interconnect network to the memory blocks on the other side of the interconnect network as shown in Figure 3.7. The efficiency of the interconnect network increases with number of parallel connections between the processors and memory blocks.

1.2 Goals and Objectives

The goal of this work is to analyze different types of interconnect networks applicable to the HDCA system. Their connection, routing mechanism, complexity are described and evaluated. This work also includes design, VHDL description synthesis and implementation of interconnect network based on a crossbar topology. Analysis will show this topology to be the one that best meets the HDCA system requirements.

The crossbar switch can provide simultaneous connections among all its inputs and all its outputs. The crossbar contains a switching element (SE) at the intersection of any two lines extended horizontally or vertically inside the switch. Circuit switching networks can be classified by the connection of the network and the relation of the network inputs and outputs [1]. The most basic distinction concerns whether inputs and outputs are differentiated or whether all ports are treated equally. Single sided networks have only one set of connections or ports, all of them are treated equally. They can be designed to meet the requirements of inter-processor communication and are unique to distributed memory systems. In distributed memory systems processors do not have to share common memory,
each processor communicates with its own local memory, hence using single sided crossbar network communication between any two processors is possible. Double sided networks connect two distinct set of ports, usually referred to as inputs and outputs. Ports in one set generally may be connected only to the ports of the other set.

The HDCA system under consideration is shared memory architecture. It will be seen the double sided crossbar network is the most suitable to be used as the interconnect network. The design will need some kind of priority logic, which prioritizes conflicting requests for memory accesses by the processors. In the HDCA system the memory is divided into blocks, each block containing memory locations with different address ranges. The interconnect design will be a combination of a double sided crossbar interconnect network, priority logic and a shared memory organization. A single bus system network is being used as a means to communicate between the CEs and data memory in a “first phase prototype” of the HDCA system [5]. The interconnect design to be developed and described in this thesis was developed specific to the HDCA system but it may possibly be used in other multiprocessor systems.

A survey of different types of interconnect networks is described in Chapter 2. Complexity of dynamic interconnection networks is discussed in chapter 3. The detailed crossbar interconnect network design is described in Chapter 4. Chapter 5 includes individual simulation testing set up and results, validation of the crossbar is done using the HDCA system, modifications to the HDCA system for proper functioning of the entire system are described. Additional functionality incorporated into the HDCA system, Dynamic Node Level Reconfigurability and Multiple Forking capability of the architecture is explained in detail and exhibited with the help of application in Chapter 6. Virtual prototype development and the testing environment is discussed in Chapter 7. Conclusions and recommendations are being included in Chapter 8.

Chapter Two

Types of Interconnect Systems

Interconnect networks can be classified as either static or dynamic [4]. Static networks can be further classified according to their interconnection pattern as One-dimension (1D), Two Dimensional (2D) and Hypercube (HC’s). Dynamic networks can be further classified according to the scheme of interconnection as bus-based versus switch-based. Bus-based networks are classified as single bus or multiple bus. On the other hand switch-based dynamic networks are classified according to the structure of the interconnect network as Single-Stage (SS), Multi-stage (MS), or crossbar networks.

![Diagram of Interconnection Networks]

Figure 2.1, A Topology Based Taxonomy for Interconnection Networks
Static networks form all connections when the machine is designed rather than when the connection is needed. In a static network, messages must be routed along established link. This means a single message must ‘hop’ through intermediate processors on its way to its destination. The nodes are the computers and the routing is done by the computers. Dynamic networks establish a connection between two or more nodes ‘on the fly’ as messages are routed along the links. The nodes are switching elements and the routing is done by the network [8] [9].

2.1 Static Interconnection Networks

The features are having fixed paths, unidirectional or bi-directional, between processors. Two types of static networks can be identified. They are ‘Completely Connected Networks’ (CCNs) and ‘Limited Connection Networks’ (LCNs) [4].

2.1.1 Completely Connected Networks (CCNs)

In a completely connected network each node is connected to all other nodes in the network. An example having nodes $N = 6$ is shown in Figure 2.3. A total of 15 links are required in order to satisfy the complete interconnectivity of the network.
These networks guarantee fast delivery of messages from any source node to any destination node, only one path has to be traversed. Completely connected networks are however expensive in terms of number of links needed for construction. This disadvantage is more severe for higher values of N.

The number of links in a completely connected network is given by \( N \frac{(N-1)}{2} \), i.e. \( O(N^2) \). The delay complexity of CCNs, measured in terms of the number of links traversed as messages are routed from any source to any destination is constant, \( O(1) \).

### 2.1.2 Limited Connection Networks (LCNs)

As the name suggests these networks do not provide a direct link from every node to every other node in the network. The length of the path for the message to traverse from source node to destination is expected to be longer compared to the paths in CCNs. Two conditions have to be taken into consideration for the LCNs, the need for a pattern of interconnection among nodes and the need for a mechanism for routing messages around the network until they reach their destinations.
2.1.2.1 Linear Arrays and Ring (Loop) Networks

Each node is connected to its two immediate neighboring nodes, except the ones at each end. If node \( a \) needs to communicate with node \( b, \ b>a \), the message traverses through nodes \( a+1, a+2... \ b-a \). Similarly if \( b<a \), the message has to traverse nodes \( a-1, a-2... \ a-b \). The worst possible case is when node 1 has to send a message to node ‘N’. The message has to traverse a total of N-1 nodes before it reaches the destination node. Hence though these systems are easy to design and have a simple architecture. They tend to be slow. This is particularly shows when ‘N’ is large.

The network complexity of a linear array is \( O \ (N) \) and time complexity is \( O \ (N) \). If the two nodes at the extreme ends of a linear array network are connected, then the resultant network has a ring (loop) architecture.

2.1.2.2 Mesh-connected Networks

An \( n \)-dimensional mesh can be defined as an interconnection structures that has \( K_0 \times K_1 \times ... \times K_{n-1} \) nodes where \( n \) is the number of dimensions of the network and \( K_i \) is the radix of dimension \( i \).
The linear array as described above is a 1-D mesh network. The mesh architecture with wraparound connections forms a ‘torus’.

A number of routing mechanisms have been used to route messages around meshes. One such routing mechanism is known as the ‘dimension-ordering’ routing. A message is routed in one given dimension at a time, arriving at the proper coordinate in each dimension before proceeding to the next dimension. Consider a 3-D mesh as shown in the Figure below. It is a 3x3x2 mesh network. Each node is represented by its position \((i, j, k)\), messages are first sent along the ‘\(i\)’ dimension then along the ‘\(j\)’ dimension and finally along the ‘\(k\)’ dimension. A maximum two turns are allowed and these turns are from ‘\(i\)’ to ‘\(j\)’ and then from ‘\(j\)’ to ‘\(k\)’. Figure 2.8 shows the route of a message sent from
node S at (0, 0, 0) to node D at position (2, 1, 2). For a mesh interconnection network with ‘N’ nodes, the longest distance traveled between any two arbitrary nodes is $O(\sqrt{N})$.

![3x3x2 Mesh Network](image)

Figure 2.8, 3x3x2 Mesh Network

Multiprocessors with mesh interconnection networks are able to support many scientific computations very efficiently. Another advantage of mesh interconnection networks is that they are scalable.

### 2.1.2.3 Tree Network

A binary tree network shown in the Figure 2.9 is an example of a tree network.

![A Tree network](image)

Figure 2.9, A Tree network

If a node at level ‘i’, assuming that the root node is at level 0; needs to communicate with a node at level ‘j’, (i>j) and the destination node belongs to the same root’s child sub tree, then it sends its message up the tree traveling node at levels $i-1$, $i-2$, ... $j+1$ until it reaches the destination node.

### 2.1.2.4 Cube- connected Networks
Cube connected networks have their interconnection network patterned after the n-cube structure. An n-cube, also called the Hypercube of order n, is defined as an undirected graph having $2^n$ vertices (0 to $2^n - 1$) such that there is an edge between a given pair of vertices if and only if, the binary representation of their addresses differs by one and only one bit.

![Figure 2.10, Cube-Interconnect Networks with Different Dimensions.](image)

In a cube-based system processing elements are positioned at the vertices of the graph. Edges of the graph represent point-to-point communication links between
processors. Each processor in a 4-cube network is connected to 4 other processors. If the source of message is at ‘i’ and the destination is at ‘j’ then route of message can be found by xoring the binary address representation of ‘i’ and ‘j’. For instance, if a message is sent from source ‘S’ node 0101 to destination ‘D’ node 1011, then the xoring operation results in 1110. This means that the message has to traverse only along 2, 3 and 4 (from left to right) in order to arrive at the destination. The order of message travel is not important. Once a message travels in any order along the three dimensions it reaches the destination node.

The hypercube is also known as logarithmic architecture. This is due to the fact that the maximum number of links a message has to traverse in order to reach its destination in an n-cube containing \( N = 2^n \) nodes in \( \log_2 N = n \) links. Another feature of the hypercube networks is the recursive nature for their construction. An n-cube can be constructed from two sub cubes each having an \((n-1)\) degree by connecting nodes of similar addresses in both sub cubes. As shown in Figure 2.9 the 4-cube network is constructed from two 3- cube networks. However it can be seen that the hypercube networks are not easily scalable.

One of the variations from the basic hypercube interconnection is the cube-connected cycle architecture. In this architecture, \(2n+r\) nodes are connected in an n-cube fashion such that groups of \(r\) nodes each form cycles at the vertices of the cube.

![Figure 2.11, Cube Connected Cycles.](image)

Figure 2.11 shows a 3-cube connected cycle network with \(r=3\). It has three nodes forming a loop at each vertex of the 3-cube.
2.1.2.5 Star Connected Network

In a star topology [6](see Figure 2.12) there is one central node processor to which all other nodes are connected, each node has one connection whereas center node has N-1 connections. The routing mechanism is trivial. If the message is routed from one of the nodes to center node the path is just the edge connecting them. If a message is routed from a source node to a destination node other than the destination node, then the message is routed from a source node to a center node and from that node to a destination node. Star networks are not feasible for large networks since the central node becomes a bottleneck.

![Figure 2.12, Star Connected Network.](image)

2.2 Dynamic Interconnection Networks

These networks include bus-based systems (single and multiple) and switch – based systems (single-stage, multi-stage and the crossbar) [4].

2.2.1 Bus-based Dynamic Interconnection Networks

2.2.1.1 Single bus Systems

They are the simplest and an efficient solution when the cost and a moderate number of processors are involved. [6]
All processors communicate with a single shared memory. Typical size of such a system is between 2 to 32 processors. However single bus systems are inherently limited by the bandwidth of the bus and also that only one single bus communication can take place at a time. The main drawback is a bottleneck to the shared memory when the number of processors becomes large and also a single point of failure hangs the entire system.

### 2.2.1.2 Multiple Bus Systems

The use of multiple buses to connect multiple processors is a natural extension to the single shared bus system. This system uses several parallel buses to interconnect multiple processors and multiple memory modules. A number of connection schemes is possible with this system [4].

- **Multiple - bus with full bus-memory connection**: All the memory modules connected to all buses.
- **Multiple – bus with single bus-memory connection**: Each memory module connected to a specific bus.
- **Multiple – bus with partial bus-memory connection**: Each memory module connected to a subset of buses.
- **Multiple – bus with class- based memory connection**: Memory modules are grouped into classes and each class is connected to a specific subset of buses.
Buses can be classified as ‘synchronous’ or ‘asynchronous’. For any event on the synchronous bus, the transaction time is taken into account. The transaction time is known apriori. In the case of asynchronous buses, the occurrence of an event is triggered by availability of data and the readiness of devices to initiate bus transactions.

2.2.2 Switch – based Interconnect Networks

Connections among processors and memory modules are made with the help of simple switches. Three basic topologies exist, they are Crossbar, Single –stage, and Multi-stage.

2.2.2.1 Crossbar Networks

All the processors in a crossbar network (Figure 2.14) have dedicated buses directly connected to all memory blocks. It represents the other extreme to the limited single bus network; it can provide simultaneous connections among all its inputs and all its outputs [1,4,10].

Figure 2.14, Crossbar Network System.
A crossbar contains a Switching Element (SE) at the intersection of any two lines extended horizontally or vertically inside the switch. It is a ‘nonblocking’ network that allows any input – output connection pattern to be executed.

The network complexity for an N x N crossbar measured in terms of number of switching points is O (N²). The time complexity measured in terms of the amount of input to output delay is O (1). In spite of high speed, their use is normally limited to those systems containing 32 or fewer processors due to increase in complexity and hence the cost.

2.2.2.2 Single Stage Interconnection Networks

In these networks a single stage of switching elements (SEs) exists between the inputs and the outputs of the network. The simplest that can be used is the 2 x 2 switching element. There could be four possible settings that such switching element can assume.

- **Straight**: Upper input is transferred to the upper output and the lower input to lower output.
- **Exchange**: Upper input is transferred to the lower output and the lower input to upper output.
- **Upper – broadcast**: Upper input is broadcast to both the upper and lower outputs.
- **Lower – broadcast**: Lower input is broadcast to both the upper and lower outputs.

A well known connection pattern for interconnecting the inputs and the outputs of a single-stage network is the ‘Shuffle-Exchange’. Two operations are used; they can be defined using an ‘m’ bit- wise address pattern of inputs, p_{m-1} p_{m-2}…p_1p_0, as given:

![Figure 2.15, Different Settings of the 2 x 2 SE](image)
\[ S (P_{m-1}P_{m-2}... P_1 P_0) = P_{m-2}P_{m-3}...P_1 P_0 P_{m-1} \]
\[ E (P_{m-1}P_{m-2}...P_1P_0) = P_{m-1}P_{m-2}...P_1 P_0 \]

Perfect shuffle operation: cyclic shift 1 place left as in 101 → 011
Exchange operation: invert least significant bit as in 101 → 100 [8]

With these operations data is circulated from input to output until it reaches its destination. The network complexity of the single stage interconnection network is O (N) and the time complexity is O (N).

2.2.2.3 Multi – stage Networks (MINs)

Multi-stage Interconnection Networks (MINS) are introduced as a means to improve some limitations of the single–stage networks while keeping the cost within limits. MINs can provide a number of simultaneous paths between processors and memory modules. The routing of a message from a given source to a given destination is based on the destination address, also called ‘Self–routing’. Each bit in the destination address is used to route the message through one stage in several of these networks[1,4,8]. The first MSB of the destination address is used to control the routing in the first stage, the next bit for stage two and so on [4][8].

MINs can be classified in a number of different ways; one of the criterions is ‘blockage’ [1,4]. Based on this criterion the MINs are classified as

- **Blocking Networks**: These networks possess the property that in the presence of a currently established interconnection between a pair of input to output the arrival of a new interconnection between two arbitrarily unused input and output may or may not be possible.
- **Re–arrangeable Networks**: These networks have the property that it is always possible to re- arrange already established connections in order to make allowance for other connections to be established simultaneously.
- **Non–blocking Networks**: These are networks that are characterized by the property that in the presence of a currently established connection between any pair of input/output, it is always possible to establish a
connection between any arbitrary unused pair of input/output without rearrangement of any existing connection.

**Omega Network**

A multi-stage interconnect network using $2 \times 2$ switch boxes and a perfect shuffle interconnection pattern between the stages is called an Omega Network [1,4](see Figure 2.16).

![Figure 2.16, 8 x 8 Omega Network](image)

In general an $N \times N$ Omega Network connects $N$ inputs to $N$ outputs where $N = 2^n$. There are ‘$n$’ stages of $N/2$ switches of size $2 \times 2$ and the input is a shuffle connection. In an Omega Network there is one unique path from each input to each output. This is an example of a ‘blocking network’.

**Benes Network**

It is a well known example of a re–arrangeable network [1,4]. Figure 2.17 shows an example 8 x 8 Benes Network. Two simultaneous connections are shown established in the network.A message is to be routed from $110 \rightarrow 100$ and $010 \rightarrow 110$. The paths are shown, one as a dotted line and another as a bold dark line [4].
The re-arrangeable property of this network can be exhibited with the following example. If a message is to be routed from 101 $\rightarrow$ 001 with the previously two paths established, the path from 110 $\rightarrow$ 100 must be re-routed. This re-arrangement is shown in Figure 2.18.

**Clos Network**

It is a well known example of a non-blocking networks. [1,4] It comprises of $r_1(n_1 \times m)$ input crossbar switches, $m(r_1 \times r_2)$ middle crossbar switches and $r_2 m \times n_2$ output crossbar switches. Generally Clos’s three stage nonblocking arrangement uses rectangular crossbars in all stages; however with an equal number of inputs and outputs, the middle switches are square. Each crossbar has one output connected to an input of each crossbar of the stage that follows, hence there always exists a possible path through each of the middle – stage switches between any input and output [1].
Figure 2.19, Clos Three-Stage Network in Block Form
Chapter Three

Multistage Interconnect Network Complexity

Chapter 2 overviewed the various types of interconnect network systems used in today’s world. The main issue in this chapter is to choose a suitable interconnect network which can be used in the HDCA system[7]. For the HDCA system, the desired interconnect should be able to establish non-blocking, high speed connections from the requesting Computing Elements (CEs) to the shared memory. The interconnect should be able to resolve any conflicts of two or more processors wanting to access the same memory block and grant access to the memory to the CE which has the highest priority. Considering this brief overview of the requirements of an interconnect network suitable for the HDCA system, it can be concluded that the non-blocking, re-arrangeable multistage or crossbar networks (Benes, Clos and Crossbar) discussed in chapter two are suitable to use in the HDCA system.

3.1 Crossbar Topology

The Crossbar provides simultaneous connections among all its inputs and outputs. It is a non-blocking, very reliable and high-speed network. An (8x 8) example is shown in Figure 3.1.

Figure 3.1, 8 x 8 Crossbar Network
A typical crossbar network with ‘N’ inputs(processors) and ‘M’ outputs(memory modules), is depicted by $X_{N,M}$. As discussed in Chapter two, the complexity of a crossbar is given by $N \times M$. Complexity increases with the increase in number of inputs and outputs. This is the main limitation of this network. This reduces the scope of scalability of crossbars [6].

### 3.2 Benes Network

The Benes network (Figure 3.2) is a re-arrangeable multistage network. [1,6] For any value of $N,d$ should be chosen so that $\log_d N$ is an integer. The number of stages for an $N \times N$ Benes network is given by $(2\log_d N - 1)$ and has $(N/d)$ crossbar switches in each stage. Hence $B_{N,d}$ is implemented with $[(N/d)*(2\log_d N - 1)]$ crossbar switches. The general architecture is as shown in Figure 3.2. As can be seen in the Figure,

- **N**: Number of inputs or outputs
- **d**: Dimension of each crossbar switch ($X_{d,d}$)
- **I**: First stage switch = $X_{d,d}$
- **II**: Middle stage switch = $B_{N/d,d}$
- **III**: Last stage switch = $X_{d,d}$

The complexity of the network is given by $[(N/d)*(2\log_d N - 1)*d^2]$. The network latency is a factor of $(2\log_d N - 1)$, since there are $(2\log_d N - 1)$ stages between input and output. There are different routing paths available between input and output. It is a limited scalability network; this and network latency are the main drawbacks of the Benes network. For very large networks Benes network implementation is cost effective.

### 3.3 Clos Network

Clos network is a non-blocking multistage network as stated in Chapter two. Figure 3.3 shows a typical $N \times M$ Clos network represented by $C_{N,M}$ [1,6]

The blocks I and III are always crossbar switches and II is a crossbar switch for a 3 stage Clos network. In implementations of higher order Clos networks, II is a lower order Clos network.
Figure 3.2, Benes Network[6]
Figure 3.3, Clos Network[6]
N: Number of processors  
M: Number of Memory blocks  
K: Number of Second stage switches  
C1: Number of First stage switches  
C2: Number of Third stage switches

For a three stage Clos network, I = X_{N/C1,K}, II = X_{C1,C2}, III = X_{K,M/C2} and the condition for a non-blocking Clos implementation is K = N/C1 + M/C2 - 1.

A three stage Clos implementation for N = 16, M = 32, C1 = 4, C2 = 8 has K = 16/4 + 32/8 - 1 = 7. Each 1st stage switch becomes a 4 x 7 crossbar switch and the 2nd stage switch becomes a 4 x 8 Crossbar switch and each third stage switch becomes a Crossbar switch of size 7 x 4. (I = X_{4,7} II = X_{4,8} III = X_{7,4}). The complexity of a Clos network is given by $C_{clos} = [K(N+M) + K(C1*2)]$. Using the non-blocking condition, K = N/C1 + M/C2 - 1. For N = M & C1 = C2, K = 2N/C1 - 1 and hence

$C_{clos} = (2N/C1 - 1) \{2N + C1^2 \}.$

For an optimum cross point count for non-blocking Clos networks, N/C1 = (N/2)^{1/2}

=> $C1^2 = 2N$

=> $C_{clos} = ((2N)^{1/2} - 1). 4N.$ (Approximately)

The Clos network can be implemented for any non-prime value of ‘N’. The main advantage of clos network implementation is scalability; however disadvantages are network latency and implementation for smaller networks.

3.4 Complexity Comparison

Table 3.1 shows the complexity comparison of the three networks discussed above. In the table ‘I’ is the complexity and ‘II’ is the corresponding network implementation for different values on ‘N’; here the number of inputs and number of outputs are assumed to be ‘N’ for simplicity in comparison.

</tbody>
</table>
Chart 1, shown in Figure 3.4, is the graph of complexity of the three topologies versus N, the number of processors or memory blocks; for lower values of N (N <= 16). Chart 2, shown in Figure 3.5, is the graph of complexity of the three topologies versus N, the number of processors or memory blocks, for higher values of N (N >= 16).

Figure 3.4, Complexity Chart for N<= 16 [6]

Figure 3.5, Complexity Chart for N>=16 [6]
The equations used for calculating the complexities of the three topologies are as follows:

\[ C_{\text{clos}} = (2N/C_1 - 1) \{2N + C_1^2\}, \]

For \( N/C_1 = (N/2)^{1/2} \), taken to the closest integer value.

\[ C_{\text{benes}} = \lceil(N/d)(2\log_d N - 1)d^2 \rceil, \]

\[ C_{\text{crossbar}} = N^2 \]

From table 3.1 and the charts in Figures 3.4 and 3.5, one can conclude that the crossbar topology has the lowest or almost equal complexity for the values of \( N<=16 \). Therefore the crossbar network is the best interconnect implementation for \( N<=16 \). This network is faster than any other network since the hardware required is less as compared to other networks. It is also a non-blocking network as there is connection capability of every input to every output. For systems having configurations of more than (16 x16) but less than (32 x32), one has to trade–off between speed and complexity, since for multistage networks like Benes or Clos, the complexity is less as compared to the crossbar network; however at the cost of speed. For systems with configurations of more than (32 x 32), the Benes network proves to be the best choice.

The HDCA system in consideration requires an interconnect network system with complexity of not more than 256 (16 x 16). Hence, from the above discussion, one can conclude that the crossbar switch is the best suitable for the HDCA system. The HDCA system as described in [5,18] has a single bus communicating between the shared memory and the computing elements (CEs). With the interconnect network acting as the communication channel between the above said components the system is as shown in Figure 3.6. The shared memory is divided into a number of blocks as can be seen in Figure 3.7. Here the number of memory blocks, ‘M’ is chosen such that \( 2^e = M \).
Figure 3.6, Multiprocessor Shared Memory Organization
Figure 3.7, Shared Memory Organization

Figure 3.8, Organization of Each Memory Block
A main issue in implementing a crossbar network is arbitration of processor requests for memory accesses. The arbitration issue comes into play when two or more processors, Computing Elements in this case, request for memory access within the same memory block. There are mainly two kinds of protocols for designing a crossbar interconnect, fixed priority and variable priority protocols. Round robin protocol, First-In First-Out (FIFO), Least Recently Used (LRU) and Last-In First-Out (LIFO) are some of the fixed priority protocols used. A fixed priority protocol assigns fixed priorities to the requesting processors. In case of conflict, the processor having the highest priority ends up having its request granted all the time. In the HDCA system, a variable priority protocol is used, here priorities assigned to processors dynamically vary over time based on some parameters of the system. In the HDCA system of Figure 1.1, all processors are dynamically assigned a priority depending upon individual input queue depth (see Figure 1.2) at any given point of time. In the case of conflict, the processor having the highest (deepest) queue depth at that point of time gets the request grant. When two processors accessing the same memory block have the same queue depth and priority is then determined by “processor identification number”. The HDCA system needs to settle some more arbitration issues for processor conflicts. A detailed design of the implementation is described in the next chapter.
Chapter Four

Design of the Crossbar Interconnect Network

A detailed design of the crossbar interconnect network suitable for integration into the HDCA system is described in this chapter. A general overview of the organization of the computing elements, the crossbar interconnect and the shared memory with blocks is shown in the Figure 3.6. In this figure PI[i] represents the bus structure between Processor and Crossbar Switch. IM[i] represents bus structure between Crossbar Switch and Memory Blocks. The Figures 4.1a and 4.1b shows the detailed diagram of both the bus structures.

4.1 Organization of Shared Memory

The utilized shared memory organization used is shown in Figures 3.7 and 3.8. From Figure 3.7, there are \(2^c = M\) memory blocks and the organization of each memory block is shown in Figure 3.9. In each memory block, there are \(2^b\) addressable locations, of ‘a’ bits width. Hence the main memory which includes all the memory blocks has \(2^{b+c}\) addressable locations of ‘a’ bits width. Therefore the width of the address bus of each processor is \((c + b)\) bits wide and the data bus of each processor is ‘a’ bits wide. For the address bus “c” represents the most significant bits of the bus and “b” represents the least significant bits of the bus.

4.2 Basic Design of Crossbar Switch

Refering to the Figures 3.7 and 4.1a and 4.1b the signal ctrl[i] goes high when the processor is requesting a connection to a particular memory block. The rw[i] signal goes high when a processor has to write into the memory block and goes low when it has to read out from a memory block. The qdep[i] is the queue depth of the processor[i], addr_bus[i] is the \((b+c)\) address of the memory location where ‘c’ is the block address with which the processor wants to communicate. flag[i] is an output of the crossbar switch; it goes high when the processor request is granted access to the memory block. The value of flag[i] is decided by a priority logic which is described in a later section. The bit widths of ‘ctrl[i]’, ‘rw’ and ‘flag[i]’ remain one bit, however the bit widths for
other inputs and outputs can vary. The design is adaptable to any number of processors and memory blocks.

Using Figure 4.2a, a generic representation of the interconnect to understand the working of the crossbar, lets take an example of processor[i] requesting access to memory block[j] represented by MB[j]. This means ctrl[i] goes high and the ‘c’ bits of addr_bus is ‘j’. Processor[i] gets connected to the bus D[i][j], through a decode logic D[i] as shown in Figure 4.2a. The address is decoded by the decoder and connection is established between processor[i] and D[i][j]. Every memory block has a priority logic block ‘prl_behav[j]’ as shown in Figure 4.2 and 4.4. The function of this logic block is to grant access to a processor having the deepest queue depth among the processors requesting access to the same memory block. Once a processor gains access to a memory block indicated by the flag[i] going high, the connection between the processor[i] and the memory block MB[j] is established and data flow from or into the memory takes place depending on the value of rw[i]. This connection stays active as long as the processor holds deepest queue depth or the request for the memory block by processor that is ctrl[i] is high. For the case of processors having the same queue depth the processor having highest processor identification number gets the highest priority. Each priority logic block sets a value of ‘sub_flag’; these values are re-evaluated again if the situation of two or more processors requesting access to the same memory block arises. Otherwise, there is no change in the evaluation of ‘flag’. This is achieved by a combinatorial logic refer to Appendix[A2] A flow chart showing the algorithm of the priority logic block in the Figure 4.4; is shown in the Figure 4.5. The mbaddr[x] signal shown in the flow chart corresponds to the ‘c’ MSBs. The flag[i] signal in Figure 4.5 is shown as signal sub_flag[i] in Figure 4.4. The number of computing elements or processors is assumed to be four in this case; however this logic holds good for any number of processors. The processors whose ctrl signal is high that is those requesting access to the memory are considered for the algorithm in discussion.
Figure 4.3, Decode Logic D[i]

Figure 4.4, Priority Logic Block
Figure 4.5, Flow Chart for the Priority Logic Block in Figure 4.4
The block compares current maximum queue depth with the queue depth of every processor starting from the 0th processor. The integer values ‘i’ shown in the Figure 4.5 is the processor identification number, having the deepest queue depth at that particular instant. Once the comparison is done as depicted in the Figure 4.5 the flag[i] goes high, granting the access to the particular processor satisfying the logical criteria explained in the flow chart.

Thus it can be seen that the interconnect network described here gives all the processors the choice of simultaneous access to the shared memory, granted by the priority logic. The best case scenario is when all the processors have their requests granted by the priority logic. This is possible when all processors are requesting access to different memory blocks that is no two processors have the same ADDR_BLK.

The crossbar interconnect is described in VHDL using two different approaches. One is a behavioral approach; it has a single function which describes the processor prioritization done by the priority logic blocks. The VHDL code for this approach is in Appendix A1. The other is a component level (RTL level) model of the crossbar switch. This particular model has basically two types of components; the decode logic block and a priority logic block. Each processor has a pair of decoder and priority logic blocks between the processor and the memory block. The VHDL code of the interconnect is shown in Appendix A2.

![Figure 4.1a, Pi[i] and Di[j] Bus Structure](image)
A graph of the number of gates required in implementation of different sizes of interconnection networks was plotted as shown in Figure 4.6. It shows that it scalable for smaller designs. However the projected values of the gate count for values greater than 16 are expected to shoot up exponentially. The exact values could not be found out for networks greater than 8x8, since the network could not fit in the largest FPGA chip available in Xilinx 6.2.3i package.

Chapter Five

Implementation of Variable Priority Interconnection and Virtual Prototype
Validation of Correct Independent Operation and Operation as the
Processor-Memory Interconnect of the HDCA

5.1 VHDL Design Capture

As explained in Chapter 4, the crossbar interconnect design capture in VHDL has been achieved two different ways. One is a behavioral approach [6](see Appendix A1) and the other is a component level (RTL level) approach(see Appendix A2). The structural equivalent of the behavioral description is shown in Figure 5.1. The component level approach is structurally outlined as shown in Figure 4.2a and 4.2b of chapter 4. The variable priority crossbar interconnect of [6] was validated to function correctly. It was never integrated into the HDCA. The version of this interconnect as addressed in Chapter 4, will first be independently validated in this Chapter. It will then be validated in this Chapter to perform correctly within the HDCA.

5.1.1 Modifications to Behavioral Approach

The main VHDL code [6] has a function ‘flg’, an entity ‘main’ and a process’P1’. This code is scalable(generic parameterized coding in an HDL sense) in the sense that it is possible to increase the number of processors, memory blocks, memory locations in each memory block, data width and the width of the queue depth bus. The VHDL code for the interconnect as it will be tested in the HDCA is included in the Appendix A1. Here the number of processors, the number of memory blocks and also the number of addressable locations in each memory block is assumed to be ‘4’. Queue depth of each computing element is also assumed to be four bits wide(See Figure 4.2a)

The code described in [6] was developed to be implemented with Xilinx Foundation series software hence it had to be modified in the following manner to display correct results using the Xilinx ISE 6.2i and ModelSim 5.7g CAD software packages. In [6] the function ‘flg’ consists of two ‘for-loops’ embedded in each other. This is modified to have a single ‘for-loop’ module. The revised code is attached in the Appendix A1.
5.1.2 Implementation of 4 x 4 Crossbar Interconnect

The VHDL coded interconnect network with crossbar switch integrated in HDCA [Appendix A1 and A2] are synthesized and virtually post placed and routed using Xilinx 6.2.3i CAD Tool and Modelsim 5.7g as a simulation tool. The design is tested using Xilinx XC2V 8000 from the Virtex II family of chips. It has 8 million gates configuration. The entire design development, testing and validation is done on a system with following parameters: Intel Pentium4, 3.00 GHz and 1 GB of RAM. The operating system used is Microsoft Windows XP, service pack 2.

The resource utilization and timing summary for the functionally coded crossbar switch[Appendix A1]:

**Device Utilization Summary:**

Logic Utilization:
- Number of Slice Flip Flops: 64 out of 93,184 1%
- Number of 4 input LUTs: 697 out of 93,184 1%

Logic Distribution:
- Number of occupied Slices: 353 out of 46,592 1%
- Number of Slices containing only related logic: 353 out of 353 100%
- Total Number 4 input LUTs: 697 out of 93,184 1%

- Number of bonded IOBs: 78 out of 824 9%
- IOB Flip Flops: 32
- Number of GCLKs: 1 out of 16 6%

Total equivalent gate count for design: 5,352

**Timing Summary:**

Speed Grade: -5

Minimum period: 3.455ns (Maximum Frequency: 289.436MHz)
Minimum input arrival time before clock: 23.698ns
Maximum output required time after clock: 4.840ns
Maximum combinational path delay: 24.490ns
The resource utilization and timing summary for the structurally coded crossbar switch [Appendix A2]:

**Device Utilization Summary:**

**Logic Utilization:**
- Number of Slice Flip Flops: 106 out of 93,184 (1%)
- Number of 4 input LUTs: 624 out of 93,184 (1%)

**Logic Distribution:**
- Number of occupied Slices: 318 out of 46,592 (1%)
- Number of Slices containing only related logic: 318 out of 318 (100%)
- Number of Slices containing unrelated logic: 0 out of 318 (0%)
- Total Number 4 input LUTs: 624 out of 93,184 (1%)
- Number of bonded IOBs: 78 out of 824 (9%)
- IOB Flip Flops: 32
- Number of GCLKs: 1 out of 16 (6%)

Total equivalent gate count for design: 5,256

**Timing Summary:**

Speed Grade: -5

- Minimum period: 7.836ns (Maximum Frequency: 127.616MHz)
- Minimum input arrival time before clock: 7.714ns
- Maximum output required time after clock: 5.349ns
- Maximum combinational path delay: No path found

**5.1.3 Functional Testing of a 4 x 4 Crossbar Interconnect Network**

Various scenarios tested for validation of the design are described and the results are shown in simulation tracer Figures. The values shown in the tracers are represented in hexadecimal format:

**Case 1:**

All processors write to different memory locations in different memory blocks. All the memory locations are being written. The table 5.1 gives the addresses and contents of each address after each processor does a write.

<table>
<thead>
<tr>
<th>Addr.Location</th>
<th>Data(case1,2)</th>
</tr>
</thead>
<tbody>
<tr>
<td>0000[0]</td>
<td>1</td>

</tr>
</tbody>
</table>

This method is used for all the cases described in this section and the section following it (section 5.1.4)

qdep is x”1234”.

rw: x”F”

ctrl: x”F”

Data is written in order of 1st, 2nd, 3rd and 4th data location in each memory block.
addr_bus: x"C840"  data_in: x"5151" (Value shown in the table for addr_bus and data_in as an example)
addr_bus: x"D951"  data_in: x"6262"
addr_bus: x"EA62"  data_in: x"7373"
addr_bus: x"FB73"  data_in: x"8484"

Case 2:
All the processors reading out the data written in case 1. Hence all the parameters remain the same except for r_w. The result of both the cases is observed in the simulation tracer 1 (see page 47)

rw: x"0"

Case 3:
qdep :x"1234"

rw: x"0"

addr_bus: x"CD56"

Processors ‘0’ and ‘1’ try to access the same memory block ‘1’. However since the ‘qdep’ of processor ‘0’ (qdep=4) is greater than processor ‘1’ (qdep=3), processor ‘0’ is granted access to read out the value ‘7’ (addr. location: 6)

Similarly processors ‘2’ and ‘3’ try to access the same memory block ‘3’. However the ‘qdep’ of processor ‘2’ (qdep=2) is greater than processor ‘3’ (qdep=1). Processor ‘2’ is granted access to read out the value ‘6’ (addr. Location: D)

The result observed in the simulation tracer 1 (see page 47)

Case 4:
qdep: x"2244"

rw: x"0"

addr_bus: x"CD56"

This is a situation where two processors are accessing the same memory block and both of them have same ‘qdep’. The processor with highest processor number is granted access. As can be seen from the simulation tracer 2 (see page 48) that processor ‘1’ gains access to memory block ‘1’ and processor ‘3’ to memory block ‘3’.
Processor 1 reads out ‘6′ from location ‘5′
Processor 3 reads out ‘5′ from location ‘C’

**Case 5:**

qdep:x”1234”

rw:x”F”.

addr_bus:x”CD56”

data_in: x”AAAA”

Situation similar to case 3 as described above.
Here processor ‘0’ and processor ‘2’ gain access to the memory blocks ‘1’ and ‘3’ respectively.
Processor ‘0’ writes in ‘A’ at location ‘6’
Processor ‘2’ writes in ‘A’ at location ‘D’

**Case 6:**

All the parameters kept same except for rw.

rw:x”0”

The values written in case 5 are observed in this case. The result can be viewed in the Figure simulation tracer 2(see page 48).

Data_out: x”5A6A”

**Case 7:**

Situation where all the four processors access the same memory block 2.

addr_bus:x”BA98”

rw:x”F”

data_in:x”CCCC”

The qdep is the same for all.

qdep:x”2222”
According to the logic designed the processor ‘3’ with the highest processor number gains access to the memory block ‘2’. The result observed in the simulation tracer 2 (see page 48).

**Case 8:**
Read out the value written in case 7. The processor ‘3’ gained access and wrote ‘C’ at location ‘B’.
The result observed in simulation tracer 2 (see page 48).

**Case 9:**
All the cases described so far had \( ctrl \) as ‘F’.
In this case we observe the results changing the \( ctrl \).

\[
\begin{align*}
\text{ctrl:} & \ x”3” \Rightarrow “0011” \text{ in binary.} \\
\text{rw:} & \ x”F” \\
\text{data_in:} & \ x”BBBB” \\
\text{addr_bus:} & \ x”FA32” \\
\text{qdep:} & \ x”4565”
\end{align*}
\]
Processor ‘2’ and ‘3’ are not requesting access to the memory.
Processor ‘0’ and ‘1’ are requesting access for the same memory block ‘0’.
However processor ‘1’ gains the access since its qdep(=6) is greater than qdep(=5)
processor ‘0’. Processor ‘1’ writes ‘B’ at location ‘3’
The result observed in the simulation tracer 3 (see page 49).
The next stage is reading out the value written

\[
\begin{align*}
\text{Data out:} & \ x”CDBA” \\
\text{Addr_bus:} & \ x”FA32”
\end{align*}
\]

**Case 10:**
Case where none of the processors are requesting access to the memory blocks.

\[
\begin{align*}
\text{ctrl:} & \ x”0”
\end{align*}
\]
The result observed on the simulation tracer 3 (see page 49).
There is no change in the value.
Case 1: Different 'addr_bus' to be written with values at 'data_in'

Case 2: Values fed in the system are read out

Case 3

5.1.4 Component Level Description and Testing

The main VHDL code for this module ‘gate_ic_a’ consists of two components, ‘dec_ic_a’ and ‘prl_behav’ as can be seen in the Appendix A2. This design is also scalable as the code in Appendix A1 described above. The number of processors, the number of memory blocks and also the number of addressable locations in each memory block is assumed to be ‘4’. Queue depth of each computing element is also assumed to be four bits wide.

Various test cases for the verification of design are described and the results are shown in the simulation tracer Figures, it should be noted the values shown in the tracers are in hexadecimal format.

Case 1:
All the four processors are accessing different memory blocks. Eventually all the memory locations in all the blocks are written into with data. The table gives the address and memory locations of the values fed in.

Table 5.3 Shared Memory Address Space and Contents

</table>
qdep is x"1234".

rw: x"F"

ctrl: x"F"

Data is written in order of 1st, 2nd, 3rd and 4th data location in each memory block.

addr_bus: x"C840"   data_in: x"37BF"
addr_bus: x"D951"   data_in: x"26AE"
addr_bus: x"EA62"   data_in: x"159D"
addr_bus: x"FB73"   data_in: x"048C"

Case 2:
All the processors read out the data written in case 1. Hence all the parameters remain the same except for r_w. The result of both the cases is observed in the simulation tracer 4 rw: x"0"

Case 3:

qdep: x"1234"

rw: x"0"

addr_bus: x"EF01"

Processors ‘0’ and ‘1’ try to access the same memory block ‘0’. However since the ‘qdep’ of processor ‘0’ (qdep=4) is greater than processor ‘1’(qdep=3), processor ‘0’ is granted access to read out the value ‘E’ (addr. location: 1)

Similarly processors ‘2’ and ‘3’ try to access the same memory block ‘3’. However the ‘qdep’ of processor ‘2’ (qdep=2) is greater than processor ‘3’ (qdep=1). Processor ‘2’ is granted access to read out the value ‘0’ (addr. Location: F)

Hence the value of flag is x"5"
The result observed in the simulation tracer 5.

Case 4:

qdep: x"2244"

rw: x"0"

addr_bus: x"EF01"
This is a situation where two processors are accessing the same memory block and both of them have same ‘qdep’. The processor with highest processor number is granted access. As can be seen from the simulation tracer 5 that processor ‘1’ gains access to memory block ‘0’ and processor ‘3’ to memory block ‘3’.

Processor 1 reads out ‘F’ from location ‘0’
Processor 3 reads out ‘1’ from location ‘E’

**Case 5:**

\[ qdep: x"1234" \]
\[ rw: x"5" \Rightarrow "0101" \] in binary.
\[ addr\_bus: x"EF01" \]
\[ data\_in: x"AAAA" \]

Situation similar to case 3 as described above.

Here processor ‘0’ and processor ‘2’ gain access to the memory blocks ‘0’ and ‘3’ respectively.

Processor ‘0’ writes in ‘A’ at location ‘1’
Processor ‘2’ writes in ‘A’ at location ‘F’

**Case 6:**

All the parameters kept same except for \( rw \).
\[ rw: x"0" \]

The values written in case 5 are observed in this case. The result can be viewed in the Figure simulation tracer 5.

\[ Data\_out: x"1AFA" \]

**Case 7:**

Situation where all the four processors access the same memory block 2.

\[ addr\_bus: x"7654" \]
\[ rw: x"F" \]
\[ data\_in: x"1111" \]

The qdep is the same for all.
According to the logic designed the processor ‘3’ with the highest processor number gains access to the memory block ‘2’. Value ‘1’ is written at location ‘7’. The result observed in the simulation tracer 6.

**Case 8:**
Read out the value written in case 7. The processor ‘3’ gained access and wrote ‘1’ at location ‘7’.
The result observed in simulation tracer 6.

**Case 9:**
All the cases described so far had ctrl as “F”.
In this case we observe the results changing the ctrl.

\[
\begin{align*}
\text{ctrl: } x''C'' & \Rightarrow "1100" \text{ in binary.} \\
\text{rw: } x''F'' \\
\text{data_in: } x''EEEE'' \\
\text{addr_bus: } x''FE32'' \\
\text{qdep: } x''1232'' \\
\end{align*}
\]

Processor ‘0’ and ‘1’ are not requesting access to the memory.
Processor ‘2’ and ‘3’ are requesting access for the same memory block ‘3’.
However processor ‘2’ gains the access since its qdep(=2) is greater than qdep(=1) processor ‘3’. Processor ‘2’ writes ‘E’ at location ‘E’
The result observed in the simulation tracer 6.
The next stage is reading out the value written

\[
\begin{align*}
\text{Data out: } x''1EFB'' \\
\text{Addr_bus: } x''FE32'' \\
\end{align*}
\]

**Case 10:**
Case where none of the processors are requesting access to the memory blocks.

\[
\begin{align*}
\text{ctrl: } x''0'' \\
\end{align*}
\]
The result observed on the simulation tracer 6.
There is no change in the value.
Case 1:
Different 'addr_bus' to be written with values at 'data_in'

Case 2:
Values fed in the system are read out

Figure 5.4, Simulation Tracer 4
Figure 5.5, Simulation Tracer 5

Data written in at location ‘1’ and ‘F’ is displayed

Case 3

Case 4

Case 5 and 6
Figure 5.6, Simulation Tracer 6
A brief overview of the cases discussed in 5.1.1 and 5.1.2 can be obtained from the following graph in Figure 5.7 shown below.

The parameters which decide on the priority logic as described in section 5.1.1 and 5.1.2 are ‘r_w’, ‘qdep’, ‘ctrl’, ‘addr_blk’ and processor identification number. The chart is shown considering that all the processor’s ‘ctrl’ signal is at logic ‘1’ (request for access to the data memory), ‘r_w’ could be either a ‘0’ or ‘1’ (processor could either read or write from the data memory). Hence the chart is plotted taking ‘qdep’, ‘addr_blk’ and processor identification number as the parameters. The processors which granted access are shown in solid color bars and those which are denied are transparent or clear.

At time ‘1’:
Processor 0 has queue depth of ‘4’ and requests access to block 0 (Blk0).
Processor 1 has queue depth of ‘3’ and requests access to block 1 (Blk1).
Processor 2 has queue depth of ‘2’ and requests access to block 2 (Blk3).
Processor 3 has queue depth of ‘1’ and requests access to block 3 (Blk3).
Since all the processors are accessing different memory blocks all of them are granted access as can be seen from the chart.

Figure 5.7, Brief Overview of Priority Logic for the Interconnection Switch.
At time ‘2’:
Processor 0 has queue depth of ‘4’ and requests access to block 0 (Blk0).
Processor 1 has queue depth of ‘3’ and requests access to block 0 (Blk0).
Processor 2 has queue depth of ‘2’ and requests access to block 3 (Blk3).
Processor 3 has queue depth of ‘1’ and requests access to block 3 (Blk3).
In this case as can be seen processor P0 and P1 are requesting access to the same memory block 0, however since the queue depth of processor P0 (qdep=4) is higher than processor P1 (qdep=3), the processor P0 is granted access to block 0 and processor P1 is denied access. Similarly processor P2 and P3 are requesting access to the same memory block 3, the processor P2 is granted access to the memory block 3 since the queue depth of processor P2 (qdep=2) is higher than processor P3 (qdep=1).

At time ‘3’:
Processor 0 has queue depth of ‘4’ and requests access to block 0 (Blk0).
Processor 1 has queue depth of ‘4’ and requests access to block 0 (Blk0).
Processor 2 has queue depth of ‘2’ and requests access to block 3 (Blk3).
Processor 3 has queue depth of ‘2’ and requests access to block 3 (Blk3).
In this situation again processor P0 and P1 are requesting access to the same memory block 0, the queue depth for both the processors is the same (qdep=4). Hence according to the logic described in chapter 4, processor with higher identification number (Processor P1 in this case) is granted access. Processor P2 and Processor P3 are accessing the same memory block 3 and have same queue depth (qdep =2), hence similar to the situation discussed here for processor P0 and P1 the processor P3 is granted access since it has the highest processor identification number in this case.

5.1.5 Validation of crossbar switch via HDCA system

The crossbar switching network as described in Appendix A2 is embedded in the second phase “virtual” prototype of the HDCA system. The interfacing of the crossbar switch with the entire system involved major modifications to the first phase HDCA system [5] and some enhancements to the crossbar network in Appendix A2.
5.1.5.1 Changes and Enhancements to the First Phase Prototype

The base functional model of the first phase prototype [5] of the HDCA is unable to exhibit correct results at all times using Xilinx ISE 5.2i. On careful observation it is observed that small components which constitute towards the working of the entire system were not functioning correctly. In order to get the system to work as desired some major modifications and addition of some components had to be done to the first phase system. Due to frequent software related issues in the Xilinx ISE5.2i a decision was made to shift to the higher version, Xilinx ISE6.2.3i which is a much more stable version. In this section a brief description of the modifications made are listed component wise.

PE Controller

The following problems were noted in the first phase system [5]. In the state OP11 where in values are added immediately to the register value [7], the system failed to give out correct results. As a solution to this problem a multiplexer M5 is added to the existing Memory – Register Architecture [5]. This change allowed the output value of the Instruction Register IR0 to be connected directly to the register R3. The changes made have been separately shown in the Figure 5.8. Also the subtraction operation performed was giving incorrect results. The state OP5 was unable to give correct subtraction results. Appropriate changes are made to render correct results. These changes have been incorporated in the second phase system [7].

Another problem was encountered in the data input process into the ALU of the PE. The bidirectional data bus was directly connected to the ALU input which was a combinational logic, due to this unwanted data was also fed into the system along with correct values. Finally it resulted in an output with unwanted values and incorrect results. As a solution to this problem a register is introduced in front of the combinational logic circuit, the ALU. This change allowed only the correct values to enter the combinatorial logic and outputted correct results. The diagram with both the changes made is shown in Figure 5.9.
Figure 5.9, Memory/Register Architecture with Added Features
For pipelined execution of the applications running on HDCA the control logic module had to be modified. In the work done in [1982 paper], the HDCA system is capable of running multiple copies of the same application simultaneously on the system.

Different copies of the same application are distinguished on the basis of the ‘Time Stamp’ field of the command token as shown below in Figure 5.6. For the entire set of token format refer [7]

### Command Token

<table>
<thead>
<tr>
<th>Hold Field</th>
<th>Physical Location</th>
<th>Time Stamp</th>
<th>Process Number</th>
<th>XXXXXXXX</th>
<th>Data Address</th>
</tr>
</thead>
<tbody>
<tr>
<td>31</td>
<td>30</td>
<td>24 23</td>
<td>21</td>
<td>20</td>
<td>16 15</td>
</tr>
</tbody>
</table>

An application developed in [5] is designed to meet the pipelined nature of the HDCA, however on running an application it gives out incorrect results. On a closer examination of the behavior this discrepancy was due to the signal ‘outbuf’ in the control logic module. At the end of every process execution a ‘Send PRT’ and a ‘StopL’ token is being issued by the CEs which completed the process to the PRT Mapper. The signal ‘outbuf’ as mentioned above is being used in the formation of these tokens. With multiple
copies running on the system simultaneously, it was observed that the value of first copy of ‘outbuf’ was getting overwritten by the consecutive copy of ‘outbuf’ before the value is used. This resulted in loss of data for the first application and hence abrupt termination of the first application. The code for the formation of ‘Send PRT’ and ‘StopL’ tokens can be obtained from Appendix A of [5].

A major modification had to be introduced in the system to fix this particular problem. Logic is established to differentiate among the command tokens with the help of the ‘Time Stamp’ field of the command token in Figure 5.6. An array like structure is introduced to store the data required in the formation of the ‘Send PRT’ and ‘StopL’ tokens. The command token format is also changed in the wake of this change. The bits from 15 down to 8 in the token which were don’t cares(X) are changed to all ‘1s’. Along with this change a new process ‘get_data’ is introduced in the control logic module in order to parse the command tokens appropriately. The new format of the command token is shown in the Figure 5.7

<table>
<thead>
<tr>
<th>Hold Field</th>
<th>Physical Location</th>
<th>Time Stamp</th>
<th>Process Number</th>
<th>11111111</th>
<th>Data Address</th>
</tr>
</thead>
<tbody>
<tr>
<td>31 30</td>
<td>24 23</td>
<td>21 20</td>
<td>16 15</td>
<td>8 7</td>
<td>0</td>
</tr>
</tbody>
</table>

Figure 5.10b: New Token Format for the Command Token of the HDCA

As can be seen from the format above the ‘Time Stamp’ field is 3 bits wide allowing 8 copies of the same application to run simultaneously on the system.

Another capability of this system as discussed in [3] is the ‘Dynamic Node Level Re-configurability’ where in during the execution of an application the queue builds up and on reaching a set threshold value, a new CE is configured on the fly to take up the extra load of the overloaded CE. One of the problems faced while testing this property was loss of command tokens. The system failed to parse them, resulting in a sudden termination of the entire copy of the corresponding application. A new delay state is added to the control logic module.
Dynamic Load Balancing Circuit

As a part of verifying the correct functioning of the HDCA system, numerous applications are run on it. While running one of the applications as shown in Figure 5.11, it was observed that the join operation of the processes P2 and P3 to process P4 was showing incorrect results.

![Figure 5.11, An Example of a Process Flow Graph](image)

On close scrutiny the problem was found in the ‘dynamic load balancing circuit’ module. It can be seen from the Figure above that during the join operation of P2 and P3, the register R6 as shown in Figure 2.4 of [7], is utilized to store values of the Physical Location, Process Number and the Data Location. This register is used specifically for the join operation; it stores the values of Process Number and Physical Location of the current process, P2 in this case. These values are used by the consecutive process, P3 in this case so that they map to the same resultant process P4 here. The problem in this join operation was that the system failed to understand that the operation is a join operation owing to the fact that the values stored in R6 were not being assigned to the next process. The change is documented in the Appendix A2.

Input ROM

An input ROM is designed and introduced in the HDCA system in order to input data values on which the application runs. The data is requested into the system in a particular fashion and hence a core generated module could not be used. It is observed that the data is requested every third clock cycle by the system, to facilitate transfer of
values from ROM a special signal ‘valid’ as output. Only the values that are output every third clock cycle are considered to be valid and are sent inside the system.

**Multiplier CE**

This CE is another important addition to the HDCA system enhancing its heterogeneity. Multiplication forms a major part in the applications for Digital Signal Processing and the like; earlier the applications running on the application were limited because of the lack of multiplier CE. Therefore a new Multiplier CE is developed and integrated along with the other CEs. There are various ways in which a multiplier can be designed, a few of them are Booth’s algorithm and core generated multiplier. After having carried out a survey of multipliers it is observed that multipliers designed using Booth’s algorithm consumed more power as compared to the core generated multipliers. Since the factor of consumption of low power was of prime importance a design decision was made to use the multiplier as shown in the Appendix A2. As can be seen the multiplier is not a core generated, however on synthesis it is clear that the system has utilized the core generated multiplier to infer the coded multiplier.

**Crossbar Interconnect Network**

As described in the chapter 4, in which the crossbar switch is found to be the best interconnection for the HDCA system, it is introduced and integrated with the architecture. This is a step forward in the effort to make the HDCA system more scalable and effective. One major problem faced in the first phase of the system was that of bus contention in the light of two or more processors trying to access the data memory. This issue is addressed effectively by the addition of the crossbar interconnect network. The following section consists of two applications run on the HDCA system with the crossbar embedded into the system. A design decision was made to use the component level crossbar network explained in chapter 4. It should be noted here that depending on which CE accesses the memory block (refer Chapter 4) the values stored in the memory can be viewed at the ports “mem_out_0, mem_out_1, mem_out_2, mem_out_3” for processes executed by CE0,CE1,CE2 and CE4 respectively. Similar argument holds good for their
respective address locations which can be observed at “mem_ad_out_0…3” (4 different ports). These ports are shown in all the following Figures.

5.1.6 Application 1 Described with Acyclic Process Flow Graph

![Figure 5.12, Process Flow Graph for Application 1](image)

Each process can be described in more detail as follows:
P1 – Input of ‘n’ numbers into the Shared Data Memory from the InROM.
P2 - Add First ‘n/2’ numbers inputted and store the result in Data Memory.
P3 – Add the next ‘n/2’ numbers inputted and similar to P2 store the value in data memory.
P4 – Multiply the result of P2 by value ‘k’ stored in the instruction memory of the Multiplier CE.
P5 – Divide the result of P3 by value ‘k’ stored in the instruction memory of the Divider CE
P6 – Subtract the result of P5 (Multiplication) from P4 (Division) and store the value in the data memory.
P7 – Output the final value of the result obtained in process P6.

The process flow graph described is tested by running two copies of the same application, giving two command tokens. The initialization tokens and the instruction sets are described in detail in Appendix B. For the application described the number of values inputted ‘n’ is assumed to be 10 (unsigned) and ‘k’ is assumed to be 2 (unsigned). The
command tokens are inputted after the initialization tokens. The two command tokens given are: x“0101FF03” with time stamp as “000” and x“0121FF11” with time stamp as “001”. They address the PRT mapper to map the first process P1 for both the copies. Here since none of the CEs are being used the PRT mapper allocates CE0 for both the copies of P1, as CE0 has a higher priority over CE1 on process P1. Figure 5.13 shows the two command tokens being issued to the CE0.

The first instruction issued by the interface controller of each CE is shown in the waveforms at the ports “db_pe_icm0_fin0 for CE0 and similarly for other CEs. These ports taken out are from the connection signal between individual CE and its Controller as shown in Figure 1.1. CE0 begins execution of process P1, it inputs 10 values from the input bus ‘inpt_data0’ into the shared data memory, the Figure 5.14 shows the inputting of first 5 values(all 2sin this case) into the data locations starting from x”03”of shared memory block. The Figure also indicates CEs accessing, a particular block in the memory, for instance in this case CE0 is accessing block ‘blk0’ (refer to the last two signals of the waveform in Figure 5.14). The inputting of the remaining 5 values is shown in Figure 5.15. It can be seen that the ‘rq_ipt0’ goes high whenever CE requests a value to be entered in a particular location. Consequently the ‘idv0’signal is made high, to allow the inputting of values. The values stored in memory can be viewed at the “mem_out_0”.

After the process P1 is executed, as seen in process flow graph (Figure 5.12) process P1 forks to two processes, resulting in two command tokens (x“01020003” and x“01030003”) being issued to the PRT mapper. This is depicted in Figure 5.16

PRT Mapper chooses the most available CE and allocates the processes. In this case the process P2 is mapped to CE0 since it is the most available and process P3 is mapped to CE1. The reason P3 is allocated to CE1 is that this CE is made the most available for process P3 by changing ‘ram address’ field in Load PRT Mapper Token [7]. It should be noted here that this value could be changed to get different results; this application is run as per values in Appendix B. The Figure 5.17 shows the command tokens being issued to the CEs, process P2 to CE0 (x“0302FF03”) and P3 to CE1 (x“0203FF03”). At the end of process P1 for the copy 1 of the application, the execution of process P1 for 2nd copy of the application begins, the instruction is issued by the CE0
(“9C11 3003”). In the meantime CE1 starts execution of the process P3 for the first copy (“9C03 3024”). In this case CE0 and CE1 are accessing the same memory block ‘blk0’, however not at the same time hence there are no conflicts. All these developments can be seen in the Figure 5.18.

At the end of the execution of process P1 of copy 2, two command tokens are generated by CE0 and issued to the PRT mapper, similar to copy 1. It is shown in Figure 5.19. The PRT Mapper makes a selection of the most available CE and allocates the processes to the particular CEs. Figure 5.20 shows that the PRT Mapper allocates P2 to CE0 and P3 to CE1 giving out the tokens x“0323FF11” and x“0223FF11”.

The execution of process P2 of copy 1 begins after the end of process P1 of copy 2. The instruction x“9C03 3017” is being issued to the CE0. This is shown in Figure 5.21. In Figure 5.22 it can be seen that the instruction for process P3 is issued by CE1 x“9C11 3024” and also a command token x“01050003” for the process P5 is being issued to the PRT Mapper as the execution of process P3 ends. The process P5 is a division operation as shown in Figure 5.12, the PRT Mapper allocates the process P5 to the Divider CE as can be seen from the token x“0405FF03”. The stored data values in the data memory, the result of the addition of first 5 and the last 5 values before and after the division and multiplication results and final results are shown in the appendix B.

Figure 5.21, Instruction Issued by CE0 of Process P2 for Copy 1
Figure 5.22, Instruction by CE1 of P3 Copy 2 and Command Token from PRT to CE2
The division operation is shown in the Figure 5.23, the division of value unsigned‘10’ (result of addition of last 5 values of process P3) at x”0E” by unsigned‘2’, the result unsigned ‘5’ is obtained after a 20 clock cycle delay and is stored at the same location of ‘10’ that is x”0E”. To exhibit perfect division operation the ports of the divider CE are taken out and shown in the lower part of the same Figure 5.23. At the end of the execution the Divider CE sends the command token to the PRT Mapper x”81060003” which signifies that it is a join operation. The PRT Mapper waits for the P4 process to execute and issue similar token to the PRT Mapper.

After the execution of process P2 by CE0 it sends the command token x”01040003” to the PRT Mapper. The next process is P4, multiplication operation; hence the PRT Mapper allocates the process to the Multiplier CE (CE4). It issues a command token x”0504FF03” to CE4. This is shown in Figure 5.24. The Figure also shows the issuance of instruction for process P3 for copy 2 to CE0 “db_pe_icm_0_fin0”.

Figure 5.25 elaborately shows the multiplication operation after the issue of the multiplier instruction. The value unsigned ‘10’ stored at location x”0D” (addition of first 5 values in process P2) is multiplied by unsigned ‘2’. The result, unsigned ‘5’ is stored at same location x”0D”. These values can be seen at port “mem_out_3” and locations at “mem_ad_out_3” of the waveform. The ports of the multiplier CE are taken out and shown in the waveform of Figure 5.25 to further exhibit the functioning of the multiplier CE. At the end of process P4 a command token is being issued by CE4 to the PRT Mapper x”81060003” which indicates a join process P6 similar to the Division process explained earlier.

The process P2 of copy 2 after execution sends a command token for process P5 to PRT Mapper and eventually the PRT Mapper sends the command token to the Divider CE. This is shown in Figure 5.26. The detail division operation is shown in Figure 5.27. Here the unsigned value ‘10’ stored at x”1C”, refer to Appendix B is divided by unsigned value of ‘2’. The result is stored in the same location x”1C” as shown in the waveform of Figure 5.27. Values observed at “mem_out_2” at location “mem_ad_out_2”. Similar to the division operation of copy 1 the divider ports are taken out to confirm perfect functioning of the divider CE. The following command token for process P6 is issued by CE2 to PRT mapper.

Figure 5.26, Command Token for P5 Issued to PRT Mapper, from PRT to CE2 Copy 2
Figure: 5.27 Div Op for P5 with Results, Command Token to PRT Mapper for Copy 2
In Figures 5.25 and 5.27 it can be seen that two CEs are accessing the same memory block ‘blk0’. In the meanwhile the PRT Mapper allocates CE1 to compute the process P6 of copy 1 as can be seen from Figure 5.28. The instruction x”9C03 9803 3032” for the join operation is issued to CE1. From Figure 5.12, it is understood that in the process P6 the values obtained from the result of process P4 are subtracted from result of process P5. The value unsigned ‘5’ (result of division) at location x”0D”, is subtracted from unsigned ‘20’ (result of multiplication) at x”0E” and the result unsigned ‘15’ is stored at location x”0F”. The result of the process P6 is outputted by the process P7. At the end of process P6 a command token is issued to the PRT mapper and consequently the PRT Mapper allocates the process P7 to CE0. The instruction for process P7 is issued by CE0 x”9C03 3039”. This process outputs the results of the subtraction operation in P6. Hence the result can be seen as explained earlier in Figure 5.29. Also it can be seen in the Figure the command token for process P4 of copy 2 being issued to PRT Mapper and eventually a command token x”0524FF11” seen at port “token_bus_prt_pe” issued to the Multiplier CE to execute the process P4 of multiplication.

After the command token for the process P4 is issued to Multiplier CE, the instruction is issued and multiplication takes place. The value unsigned ‘10’ stored as a result of the execution of process P2 at x”1B” is multiplied by unsigned ‘2’, the result is stored at the same location x”1B”. At the end of process P4, a command token x”81060011” for the join process P6 is issued. This is shown in Figure 5.30.

The PRT Mapper allocates the next process P6 to CE1 since it is the most available CE at that point of time. The instruction for the process P6 is given out to CE1, x”9C11 9811 3032”. This can be see from Figure 5.31. Subtraction operation takes place. The result of the process P5 (division) is subtracted from the result of P4 (multiplication) similar to the copy 1. The result is stored at x”1D”, refer to the Appendix B. The value of the final result is outputted in the next process P7. Hence after the execution of process P6 the command token to execute process P7 is given to the PRT Mapper which in turn allocates CE0, it issues the instruction x”9C11 3039”. The result unsigned ‘15’ can be seen in Figure 5.32 at port “mem_out_0” at location “mem_ad_out0” (x”1D”).

5.1.7 Application 2 Described with Cyclic Flow Graph

![Cyclic Flow Graph Diagram]

Figure 5.33, Application for Swapping of two Values

Each process shown in figure 5.33 is explained in more detail as follows:

P1 – Input 2 large values say T1 and T2 with T1>T2
P2 – Add unsigned ‘10’ to T2 to get a new value of T2.
P3 - Check if T2 =T1 orig. If yes, branch to P6 (Exit PN), display both T1 and T2
    Else branch to P2 again (feedback loop)
P4 – Subtract unsigned ‘10’from T1 and update the new value of T1.
P5 – Check if T1=T2 orig. If yes, branch to P6 (Exit PN), display both T1 and T2
    Else branch to P4 again (feedback loop)
P6 – Display the values of T1 and T2 and then exit. The values should be swapped with respect to their original locations.

There are certain modifications done to the HDCA system to function correctly for the loop application described here. The figure 5.33 shows that process P6 is a join operation it is executed only when the condition for the Exit PN is satisfied. Each time the execution of the application loops back (P3 loops back to P2 and P5 to P4) the command token generated and issued to the PRT Mapper by the CEs executing processes
P3 and P5 have the join bit field set to logic ‘1’[5]. However the next process is process P2 for P3 and process P4 for P5 rather than process P6, the actual join process. The join process check in the controller of PRT mapper is modified to handle this issue. When the condition for the Exit PN is satisfied the system should be able to properly join the two processes P4 and P5 in this case. In order for this part to function correctly the ‘StopL’ token format is modified. The bits from 15 down to 8 in the ‘StopL’ token are all at logic ‘0’ state. The bit 15 in this case is modified to be at logic’1’. This bit is used by the PRT Mapper to indicate that the token is for the real join operation. The system works perfectly with these changes made and outputs correct results refer to Appendix B.

The process flow graph shown above is tested by running a copy of an application. The initialization tokens and instruction set for processes of the application are described in detail in Appendix B. For this application the value of T1 (original) is unsigned ‘100’ and value of T2 (original) is unsigned ‘60’. As can be seen from the description of processes the values of T1 and T2 change and are different from original as the application progresses, hence the values are inputted twice into the data memory. This ensures that one of the pairs of values inputted remains intact. A command token (x”01010003”) is inputted into the system. It triggers the system to begin the application. It addresses the PRT mapper to map the process P1 to a CE which is the most available at that point of time. It is observed that PRT mapper allocates process P1 to CE0 as it has higher priority over CE1. The instruction is issued by controller of CE0 which prompts the CE0 to input values from the input ROM, it should be noted here that a new component ‘inrom’ has been added into the system in order to facilitate inputting different values of data into the system’s data memory. Figure 5.34 shows the instruction issued to CE0 indicated by port name “db_pe_icm0_fin0” (connection between interface controller module and PE) refer to Figure 1.1; the signal is taken out as the port name. The execution of the process P1 begins by inputting values from ‘inrom’. Figure 5.34 shows that two values unsigned ‘60’ and ‘100’ are input at locations x”03” and x”04”. The values can be seen at the “mem_out_0” since CE0 is executing the process. The Figure 5.31 shows the inputting of the next 3 values into the data memory. They are unsigned ‘10’, ‘60’ and ‘100’ at locations x”05”,”06” and “07” respectively. In the set of waveforms that follow it should be noted that the ports “db_req0_dbg, db_req1_dbg,
db_req3_dbg” are the signals coming from CEs 0, 1 and 3 respectively. These signals go high when the CE requests access to the memory. Similarly ports “db_grant0_dbg, db_grant1_dbg, db_grant3_dbg” are signals coming from the crossbar network to the CEs that are granted access.

At the end of process P1, it forks to two processors P2 and P4 as can be seen from 5.33. Hence two command tokens are issued by CE0 to PRT Mapper; it maps the two processes to CEs depending on the availability. It is observed that process P4 is allocated to CE0 and process P2 to CE1. In this case for process P2, CE1 is made the most available in a similar way as described in the application 1, this setting could be changed. It can be seen in Figure 5.36, the instruction for P4 is issued to the CE0 and instruction for P2 is issued to CE1. The execution of the process P2 can be seen at “mem_out_1” and corresponding address at “mem_ad_out_1” since CE1 is executing it. Similarly it can be seen that CE0 is executing the process P4 on observing line “mem_out_0” and location at “mem_ad_out_0”. The result for process P2 which is unsigned ‘70’ is stored at location x”03” and result of process P4, unsigned ‘90’ is stored at location x”04”.

At the end of each process P2 and P4, command token is issued by the CEs to the PRT Mapper which in turn finds the most available CE and maps the processes to it. Figure 5.37 shows the instruction (x”9C03 3014”) for process P3 is being issued to CE0. In this process the values unsigned ‘100’ at x”07” and value at x”03” are compared for equality. In this case the values are not equal since unsigned ‘100’ ≠ unsigned ‘70’. The execution loops back to process P2 as per the condition stated in the explanation of the processes.

Similar to process P3 which executes after P2, process P5 is executed after process P4. In process P5 also the values unsigned ‘60’ at x”06” and value at location x”04” are compared. If the values do not match, the execution loop backs to execute process P4 again. At this time the values are not equal hence the process P4 is executed again. This is shown in Figure 5.38. It also shows the instruction for process P2 issued by the interface controller of CE1 to CE1.

Figure 5.38, Process P5: First Execution

Instruction for process P5 (first execution)

Comparison of ‘60’ and ‘90’, not equal loop back to Process P4
The detail execution of process P2 is shown in Figure 5.39. The addition operation takes place and at this point of time the result calculated is unsigned ‘80’ (70 + 10) and is stored at location x”03”. It can be concluded by observing the ports “db_req0_dbg, db_req1_dbg” and corresponding “db_grant0_dbg, db_grant1_dbg” that CE0 and CE1 are accessing the same memory block (block 0). However since the CEs are accessing the same memory block the processor requesting the memory access early in time is granted access. After execution of P3 and looping back to P4, the PRT Mapper allocated process P4 to CE0 as can be seen in Figure 5.40. The subtraction of unsigned ‘10’ from value at location x”04” takes place. In this case the result calculated is unsigned ‘80’ (90 -10) at location x”04”.

At the end of process P2, the updated value is checked once again against the original value. This is done in process P3 as seen earlier. The execution of process P3 for the second time is shown in Figure 5.41. The CE0 executes this process as is seen from the instruction issued by interface controller of CE0 to CE0. Since the values compared are not equal, the application loops back to execute process P2 again. The command token x”81020003” is issued by CE0 to PRT Mapper (note the “token_bus_prt_pe” port which is a signal connecting CEs and Token Mapper, refer to Figure 1.1).

After the execution of process P4 as explained earlier, the original value at location x”06” which is unsigned ‘60’ is compared with the new value obtained as a result of process P4. This is shown in Figure 5.42. The value at location x”04” is now unsigned ‘80’. It is evident that the values being compared are not equal, hence the application execution has to loop back to execute process P4 again. The command token for P4 is issued by CE0 to PRT Mapper as shown at port “token_bus_prt_pe”: x”81040003”.

The Figure also shows the instruction for process P2 issued to CE1 by its interface controller. The execution of the process P2 and the result is shown in detail in Figure 5.43. As can be seen from port “mem_out_1” unsigned ‘80’ at x”03” (“mem_ad_out_0”) is added with unsigned ‘10’ at x”05” result unsigned ‘90’ is stored at the x”03”.

The process P4 is also executed again for the third time. The execution is done by CE0. It is shown in Figure 5.44. The value unsigned ‘80’ at x”04” obtained from earlier execution is subtracted by unsigned ‘10’ at x”05” and the result unsigned ‘70’ is stored at the same location x”04”.
Figure 5.39, Process P2: Second Execution

Instruction for process P4 (2nd execution) by CE0

Subtraction of ‘10’ at x”05” from ‘80’ at x”04”
Result ‘70’ at x”04”
At the end of process P2 again the comparison operation takes place in process P3. The values compared are unsigned ‘100’ at x”07” and unsigned ‘90’ at x”03”. Since the comparison result is not equal, it loops back again to execute P2. Figure 5.45 shows the execution of process P3 for the third time.

Similarly the process P5 is also executed again for the third time. After the execution of process P4 the updated value is compared with the original. Here new value unsigned ‘70’ at x”03” is compared with the original unsigned’60’ at x”06”. The values are not equal and hence application loops back to execute process P4. The values can be seen at port “mem_out_0” and locations at “mem_ad_out_0” of Figure 5.46. The instruction for the process P2 is also seen to be issued to CE1 by its interface controller. The detail application is shown in Figure 5.47.

The process P2 is executed again after the looping back from process P3. As seen in Figure 5.47 process P2 is executed by CE1 and the results can be viewed at port “mem_out_1” and locations at “mem_ad_out_1”. In this case unsigned value ‘90’ at location x “03” added to value unsigned ‘10’ at x”05” to get the result unsigned value ‘100’ at x”03”. One can also observe the requests and grants port lines depicting that both CE0 and CE1 are accessing the same memory block ‘0’.

Process P4 is also executed again as a result of looping back from process P3. This process is executed by CE0 as seen from the Figure 5.48. Observing port “mem_out_0” and locations “mem_ad_out_0”, the subtraction operation and the result can be seen. The value unsigned ‘10’ at x”05” is subtracted from updated value at location x”04”, unsigned ‘70’ in this case. The result unsigned ‘60’ is stored at x”04”.

After the execution of process P2 for the fourth time the process P3 is executed again by CE0. The value at x”03” unsigned ‘100’ is compared with the original value unsigned ‘100’ at x”07”. The result of the comparison is satisfied that is the two values compared are equal. Hence the condition for exiting the loop is satisfied, the application proceeds to execute process P6 which is a join operation as can be seen in Figure 5.33. This is shown in Figure 5.49.
Figure 5.45, Process P3: Third Execution

Instruction for process P3 (4th comparison)

Comparison of ‘100’ at x”07” and ‘100’ at x”03”, **equal** hence proceed to join Process P6
Command token issued to PRT mapper
It can be observed from all the Figures in this application that the signal ‘state’ is taken out from all the interface controller modules as a port. The controller for CE0 goes into the ‘StopL’ state since the Exit Loop condition is satisfied. CE0 issues a command token x”81060003” to the PRT mapper. The mapper waits for other join token which is sent by process P5 after the exit PN condition is satisfied.

The process P5 is executed by CE0 and the instruction is issued by its interface controller, it is shown in Figure 5.50. The value at location x”06”, ‘60’ (unsigned) is compared with updated value unsigned ‘60’ at x”04”. The values are equal and hence the condition for the Exit loop is satisfied. The execution proceeds to process P6 and CE0 issues a command token x” 81068003” similar to process P3 as described earlier. The state of the controller of CE0 goes into the ‘StopL’ state.

The PRT Mapper receives both the tokens of the join process P6. It maps CE1 as the most available CE to execute process P6. The instruction is issued by CE1 interface controller to CE1. The values can be seen at the port “mem_out_1” and locations on “mem_ad_out_1” port. It can be observed that the values ‘100’ (unsigned) which was at x”04” and ‘60’ (unsigned) at x”03” are swapped with respect to the locations. At the end of process P6 the value ‘100’ (unsigned) is at x”03” and value ‘60’ (unsigned) is now at x”04”. This is shown in Figure 5.51.

Figure 5.51, Process P6 Join Operation, Final Results, Values Swapped
5.1.8: Latency and Starvation Issues

Latency or delay within a crossbar switch, measured in terms of the amount of the input to output delay, is a constant. [4] The crossbar possesses a constant rate of delay. It is observed that the time required for the grant signal to go high after a request signal is made high by a CE is two and half clock cycles. Once the connection is established between the CE and memory block it takes one clock cycle to read out values from the memory and also one clock cycle to write in data. These delays can be observed from the waveforms shown for the execution of applications described above in section 5.1.3 and 5.1.4.

Chapter 3 discussed choosing the arbitration technique for processors requesting memory access. A variable priority arbitration scheme is used in the design of the crossbar in this case. The priority is based on the value of the queue depth of individual processors [5] [7] [15]. In case there is contention for the same memory block the processor with the highest memory block is granted access. The issue of starvation may arise when the processor, granted access to the memory block continues to request for memory access. In this case the other processors requesting memory access have to wait for an indefinite time until the processor having high priority ceases to request memory access. This can be a serious problem in interconnection networks and has to be given special attention. Fortunately, in this situation where the crossbar switch is being used in a HDCA system, this issue is taken care off. According to the design of the HDCA architecture [5,7,15] the PRT mapper allocates process requests to the individual CEs according to their availability at that point of time during an application run. The availability is determined by tokens lined up in the queue of the processors. Hence in a situation where in processor with highest priority keeps on getting access to the memory block, the PRT Mapper eventually assigns the new processes to the other CEs since the processor with highest priority already has deeper queue depth already. After some time the processor which had been granted access, no longer has the highest (deepest) queue depth and hence the access to the memory ceases. This allows the other processors to access the memory blocks.
However, in other systems where the crossbar could be used in an environment different from the HDCA system, one way to overcome this issue is to make use of the operating system used. The amount of time any processor can be granted access to the memory block could be preset to a certain amount. Once any processor is granted access the operating system should start the timer and at the end of the preset time check if the processor still has access to memory and if yes, then it should be removed at the end of the stipulated time making provision for other processors to gain access to the memory.
Chapter Six

Dynamic Node Level Reconfigurability and Multiple Forking Capability

6.1 Concept of Node Level Reconfigurability and Changes to HDCA

For the applications developed and described in Chapter 5, a static resource allocation algorithm is first executed to statically assign specific application process to specific processors within the HDCA system prior to execution of the application. However, in many cases especially in real time applications, unexpected events may occur. This may lead to a sudden increase of input values exceeding the limits assigned during static allocation. At this time it is required that additional copies of processes, on the fly, be assigned to existing or newly configured processors within the HDCA. This is the concept of node level reconfigurability.

In order to implement this concept in the HDCA system another stand by CE is introduced to the architecture. It triggers when both CE0 and CE1 get overloaded. The maximum queue depth of the processors is set to ‘8’ (unsigned). However the threshold value is selected as ‘5’ (unsigned). The value of the threshold is chosen less than the maximum that is ‘8’ to avoid any loss of tokens that may occur in transition of issuing the token to a stand by CE rather than the overloaded one and also to provide sufficient tolerance to the system. The threshold for each of the CE0 and CE1 is set by feeding in two Load Threshold tokens as shown in Figure 6.1, for a list of all tokens refer [7]. The value of the threshold for both CEs is set to ‘5’ (unsigned) by inputting tokens x”83E80005” for CE0 and x”82E80005” for CE1.

<table>

<tbody>
<tr>
<td>1 11101 XXXXXXXXX 10 9 6 5 0</td>
</tr>
</tbody>
</table>

Figure 6.1, Load Threshold Token Fed Into HDCA Setting the Value of Threshold Flag

A design decision to trigger the stand by CE is made on the basis that when both the CEs reach their threshold value of ‘5’ (unsigned). At this point the token instead of being issued to either of the CE0 or CE1 is being given to the stand by CE. The controller
of the PRT Mapper is modified, a check is put if the threshold value of both the CEs is reached and if true the new token is issued to the stand by CE.

The application used to describe and verify the concept of the node level reconfigurability is that explained in 5.1.5. In order to make the system compute intense 8 command tokens are being fed into the system instead of one as in 5.1.5. The waveforms are captured; whenever the threshold for the CE0 and CE1 is reached the stand by CE is triggered is observed.

The command tokens fed in the system are:

x"0101FF03"  x"0121FF09"  x"0141FF0F"  x"0161FF15"

x"0181FF1C  x"01A1FF21"  x"01C1FF28"  x"01E1FF2E"

The command tokens input into the system and the two load threshold tokens are shown in Figure 6.2. The tokens can be seen on “op_token_bus”. The “prog_flag” is set to ‘5‘unsigned for CE0 at 6200 ns in the waveform.

Figure 6.3 shows that process 1 is being executed for the first four command tokens. The instructions can be seen at “db_pe_icm0_fin0” for CE0 and at “db_pe_icm1_fin1” for CE1. Also “prog_flag” for both the processors CE0 and CE1 is set to ‘5’ from the load threshold token. The signals “avlsig0”, “avlsig1” and “avlsig5” show the queue depth values of CE0, CE1 and stand by CE respectively. The values of the “avlsig0” and “avlsig1” vary from 0 to 2 as can be seen. The value does not increase beyond that since the process P1 is not complete for all the command tokens and hence have not yet forked to two processes each. As explained in 5.1.5 each process P1 forks to two processes in effect generating two command tokens issued to the PRT Mapper.

Figure 6.4 shows that forking has been done for some of the command tokens as can be seen from the instructions at “db_pe_icm0_fin0” and at “db_pe_icm1_fin1”. Most of the tokens are being issued to CE1 and its queue depth increases as can be seen from the Figure 6.4. It reaches the threshold value of ‘5’ and hence the threshold flag, “th_flag” for CE1 is set to ‘1’ around 39.5 us. However, in this case since CE0 is not yet reached its threshold the stand by CE is not triggered.
Figure 6.2, Input of two Load Threshold and Eight Command Tokens in the System
Figure 6.3, Process P1 for First Four Command Tokens
Figure 6.4, Forking of Tokens and Queue Depth of CE1 Reaching Threshold Value
The tokens generated after forking of P1 for all the eight command tokens are more or less distributed and assigned equally to the two CEs, CE0 and CE1. Hence at time 68 us as can be seen in Figure 6.5, both the threshold flags are set to ‘1’, now the stand by CE gets triggered. It can be observed that the following token which is x”0645FF0F” for process five of the third command token is being issued to stand by CE instead of being issued to CE0 or CE1. In that case the tokens would have been x”0345FF0F” and x”0245FF0F” for CE0 and CE1 respectively. It can also be shown that “avlsig5” goes from “00” to “01” and returns to “00” once the process starts executing on the stand by CE. The token issued to the stand by CE can be observed on “token_bus_prt_pe”.

During the course of execution of the application this situation arises many times and stand by CE is triggered to take off the extra load of the CEs. Another such situation is shown in Figure 6.6. The threshold for both the CEs sets to ‘1’ at around 80.5 us and the next following token is being issued to the stand by CE. The token x”0685FF1C” is seen on “token_bus_prt_pe”.

Thus it can be concluded from the waveforms that the design modifications to the HDCA in order to incorporate the node level reconfigurability works correctly.

6.2 Multiple Forking Capability of the HDCA System:

The applications described thus far as in chapter 5 had a major limitation in terms of parallelism; processes being executed simultaneously. The number of processes that a single process could fork to is limited to two. One of the ways this problem could be overcome is described here.

It can be seen from the Figure 6.6 that a process that forks into three processes is initially divided into two main processes one of which is the dummy process that just helps to fork the processes further into two processes. In the dummy process the processor goes into a “no-op” state causing a delay and forking into two processes. This can be seen as a “cascading effect”, with this method a process can be made to fork to ‘n’ number of processes.

In order to incorporate this concept into the HDCA system, an additional state ‘OP13’ is added to the controller of the PE. This state as stated earlier is a ‘no-op’ state that basically forks into two processes. The code for the additional state is included in the Appendix B.

Figure 6.6, Multiple Forking Concept Used in the HDCA System
6.3 Application Describing Multiple Forking in HDCA System:

Each process shown in the Figure 6.7 is explained in more detail as follows:
P1 – Input 6 numbers into the system.
P2 – Sum the first two numbers inputted.
P3 – Dummy Process that forks into processes P4 and P5.
P4 – Sum of the middle two numbers that is 3rd and 4th numbers inputted.
P5 - Sum of last two numbers inputted.
P8 – Subtract the result of P5 from result of P4.
P7 – Multiply the result of process P2 with ‘4’ (unsigned).
P8 – Add the result of process P7 and P8 and display.

A series of tokens are inputted into the system and finally a command token x"01010003" is fed in, as shown in Figure 6.8

Figure 6.9 shows the instruction for the first process P1 “9C03 3003”. Six numbers are inputted into the system all unsigned ‘2’ s in this case. The end of process P1 results in three processes, P2, P4 and P5 to achieve this forking as discussed earlier P1 forks to P2 and P3. P3 is a dummy process which facilitates further forking into P4 and
P5 as shown in Figure 6.7. The Figure 6.10 shows the execution of process P2, it is addition of unsigned ‘2’ at locations x”03” and x”04”. The result unsigned ‘4’ is stored at location x”0A”. The Figure also shows the token for process P3 x”02030003”.

Figure 6.11 shows the execution of process P3 which is a “no-op” with instruction “9C03 3000” and also execution and result of process P7. Process P7 is a multiplication process the result of process P2 which is unsigned ‘4’ is multiplied by unsigned ‘4’. The result unsigned ‘16’ is stored at x”0A”. It can be viewed at “mem_out_3” and at location “mem_ad_out_3”.

The execution of dummy process P3 results in two processes P4 and P5. The Figure 6.12 shows the instructions for process P4 x”9C03 3018” and x”9C03 3020” for process P5. The result for both the processes can be observed unsigned ‘4’ (“mem_out_1”) at locations x”14” for process P4 and unsigned ‘4’ (mem_out_1”) at x”1E” for process P5.

Figure 6.13 shows the instruction x”9C03 9803 3028” for the join operation of process P8 as shown in Figure 6.7. It is a subtraction operation, the result of process P4 is subtracted from result of P5. Hence the value of the subtraction operation is unsigned ‘0’ (unsigned ‘4’ at x”14” subtracted from unsigned ‘4’ at x”1E”). The result is ‘0’ (unsigned) is stored at location x”28”. The Figure also shows the token for the join process P6 being issued to the PRT Mapper by the CE, x”81060003”.

The instruction for final process P6 x”9C03 9803 3030” is shown in Figure 6.14. The process consists of addition operation; the result of P7 is added to the result of P8. The result unsigned ‘16’ (unsigned ‘16’ at location x”0A” added to unsigned ‘0’ at x”28”) is stored at location x”3C” as can be seen at “mem_out_1”.

FPGA Resources Utilized in HDCA Virtual Prototype Development and Testing Environment

The VHDL coded interconnect network and the entire HDCA system with crossbar switch integrated in it [Appendix A1 and A2] are synthesized and virtually post placed and routed using Xilinx 6.2.3i CAD Tool and Modelsim 5.7g as a simulation tool. The term ‘virtual prototype’ signifies that the system is validated using the Modelsim Simulator and shows correct results for the ‘Simulate Post-Place and Route VHDL Model’. This is the final step before actually downloading the system design onto a prototype board.

The design is tested using Xilinx XC2V8000 from the Virtex II family of chips. It has 8 million gates configuration. The entire design development, testing and validation is done on a system with following parameters: Intel Pentium 4, 3.00 Ghz with 1 GB of RAM. The operating system used is Microsoft Windows XP, service pack 2.

Among the various applications developed with the crossbar switch embedded in the HDCA system, two are tested for the post place and route simulation. The resource utilization and timing summary for application 1: Acyclic Application shown in Figure 5.12 is given below:

Chapter Eight

Conclusion

A modular and scalable architecture and design for a crossbar interconnect network of a HDCA single chip multiprocessor system is presented. The design capture, synthesis, simulation is done in VHDL using XILINX ISE 6.2.3i and ModelSim 5.7g CAD soft wares. The design is individually validated and integrated in the main HDCA system and validated again against two varied applications. The inclusion of crossbar switch in the HDCA architecture involved major modifications in the HDCA system and some minor changes in the design of the switch. The results show perfect functioning of the crossbar network. Dynamic Node Level reconfigurability feature added to enhance the HDCA capability is also tested against the acyclic application and shows proper functioning. The architecture is limited in terms of a process forking to maximum of two processes; this shortcoming is overcome and is tested by an application and exhibits perfect functioning of the system.

Building up a complete full proof architecture with all the capabilities is an on going process. With the work done in this thesis certain goals are achieved as listed above and described in detail in the earlier chapters; however there is still lot of work to be done before architecture could be used for more serious applications. One of the biggest challenges lies in the development of an Operating system. Some of the important functions that the operating system [3] should do are to perform all initialization operations and monitor the entire system in general and also detect failures, bottlenecks and quickly reconfigure the system to overcome the problem. With the integration of interconnect switch in the system the operating system should keep track of which processors are requesting access to which memory blocks on timely basis so that the condition of data incoherency does not arise.

Contents of the shared data memory:

For the copy 1 of application, the data stored in the data memory is decimal ‘2’ from location x”03” to x”0C”. The data location after addition of first five numbers is stored in location x”0D” and similarly the result of the addition of the next five numbers is stored at x”0E”.

The value changes after the division and multiplication process takes place. The table shows the values before and after the division and multiplication operation. The final result decimal ‘15’ is stored at location x”0F”.

<table>
<thead>
<tr>
<th>Address Location</th>
<th>Result before Multiplication and division (decimal)</th>
<th>Result after multiplication and division (decimal)</th>
</tr>
</thead>
<tbody>
<tr>
<td>0D</td>
<td>10</td>
<td>20</td>
</tr>
<tr>
<td>0E</td>
<td>10</td>
<td>5</td>
</tr>
</tbody>
</table>

For the copy 2 of application, the data stored in the data memory is decimal ‘2’ from location x”11” to x”1A”. The data location after addition of first five numbers is stored in location x”1B” and similarly the result of the addition of the next five numbers is stored at x”1C”.

The value changes after the division and multiplication process takes place. The table shows the values before and after the division and multiplication operation. The final result decimal ‘15’ is stored at location x”1D”.

<table>

**Process P7:**

Contents of Instruction Memory for Multiplier CE

<table>
<thead>
<tr>
<th>Instruction Memory Address</th>
<th>Data</th>
<th>Operation</th>
</tr>
</thead>
<tbody>
<tr>
<td>04</td>
<td>0007</td>
<td>OFFSET ADDITION</td>
</tr>
<tr>
<td>05</td>
<td>0004</td>
<td>MULTIPLICAND VALUE</td>
</tr>
</tbody>
</table>

One command token was entered for the test bench and its value was x’01010003’

Final Results in the Shared Data Memory is “16” at location “60”.
