Introduction

The critical importance of pasture production to New Zealand’s economic performance has been widely recognised. However, a number of critical issues have been identified that limit dairy industry growth, including sub-optimal pasture condition and poor pasture persistence. Dairy farm systems in the Waikato and Bay of Plenty provinces in the upper North Island of New Zealand are predominantly pasture-based, with a temperate climate and they represent around 30% of New Zealand’s total number of dairy farms (LIC and DairyNZ, 2012). This project was established to quantify pasture performance and identify factors that drive that performance. We established a network of on-farm trials where case studies of pasture renewal practices and outcomes were developed. Ten farms in each province were monitored for three consecutive years – four paddocks from each province are considered here.

Methods

Farm/paddock selection

All paddocks were renewed at the beginning of the trial using a variety of methods and range of ryegrass/endophyte combinations (Table 1). Soil fertility varied widely, from 26 to 160 ppm Olsen P and annual average rainfall ranged from 1150 to 2070 mm over the three years of the trial.

Measurements

Net herbage accumulation (NHA) and composition were measured by harvesting the accumulated forage regrowth at intervals of 3-8 weeks, depending on time of year, for three years post establishment. The pasture was harvested at the three leaf stage and was cut to a height of around 3 cm (approximately 1500 kg DM/ha). NHA was then aggregated into seasonal totals: ‘summer’ (Sept-Feb) and ‘winter’ (Mar-Aug). Samples were dissected into sown grass, other grasses, clover and weed fractions and dried. Growth rates for each fraction were then calculated. Soil samples were collected annually from each paddock; 40-50 cores (2 cm diameter x 7.5 cm depth) from each paddock were sampled from a diagonal transect line and analysed for soil phosphorus (Olsen P). Daily, seasonal and annual weather records were sourced from NIWA (Virtual Climate Weather Station Data; Tait et al. 2006) for the duration of the trial period (2009-2012). Data were analysed using correlations and regressions to determine the effect of break crop length, rainfall and soil fertility on total and seasonal pasture production.

Results

Pasture production/composition

Total annual pasture NHA varied from 12.7 t/ha/yr to 23.6 t/ha/yr (Table 2). ‘Summer’ NHA varied from 8.6 t DM/ha to 15.0 t DM/ha (Table 2). A high proportion of the total production (50-89%) was from ryegrass on all farms and across all seasons (Fig. 1). Soil fertility varied widely, from 26 to 160 ppm Olsen P and annual average rainfall ranged from 1150 to 2070 mm over the three years of the trial.

Paddock effects

Break crop. Paddocks that spent time in a break crop tended to have a reduced proportion of other grasses and broad-leaved weeds, although this was not statistically significant (P>0.05). Time spent in a break crop did increase the clover proportion of the sward from 3 to 13% (R²=0.59, P<0.05). There were no statistically significant effects on NHA or composition from cultivation.

Soil fertility. Total annual pasture NHA was positively related to soil P (R²=0.62, P<0.05).

*‘summer’ = September-February inclusive; + ‘winter’ = March-August inclusive

Figure 1. Average pasture growth rate and composition of eight renewed paddocks from the Waikato (WAI) and Bay of Plenty (BOP) regions of New Zealand, over four years aggregated into two seasons: ‘summer’ (September-February) and ‘winter’ (March-August). BL = broad-leaf weed.

Rainfall & soil moisture: Total annual rainfall and seasonal rainfall (summer/winter) had no significant effect on pasture production or composition (P>0.05). Average annual rainfall was 1530 mm/yr in Waikato and 2030 mm/yr in the Bay of Plenty.

Conclusion

Time spent in break crops had beneficial effects on pasture composition, increasing the clover content of the new pasture. This result was demonstrated for at least four years and is consistent with the findings of Gerard et al. (2009). Olsen P was an important driver of pasture production with higher NHA at higher soil P concentrations. However, there were too few data points to reliably identify the optimum soil P concentration (see Mackay et al. 2010).

Acknowledgements

Many thanks to DairyNZ and the Sustainable Farming Fund for providing funding for this project. We are also grateful for the additional support of Ballance Agrinutrients, Agricom, PGGW Seeds, Agri seeds, BoP Regional Council, and Waikato Regional Council.
