ABSTRACT

The nature of warm, ionized gas outside of galaxies may illuminate several key galaxy evolutionary processes. A serendipitous observation by the MaNGA survey has revealed a large, asymmetric Hα complex with no optical counterpart that extends ≳87 (≈6.3 kpc) beyond the effective radius of a dusty, starbursting galaxy. This Hα extension is approximately three times the effective radius of the host galaxy and displays a tail-like morphology. We analyze its gas-phase metallicities, gaseous kinematics, and emission-line ratios and discuss whether this Hα extension could be diffuse ionized gas, a gas accretion event, or something else. We find that this warm, ionized gas structure is most consistent with gas accretion through recycled wind material, which could be an important process that regulates the low-mass end of the galaxy stellar mass function.

Key words: galaxies: abundances — galaxies: evolution — galaxies: formation — galaxies: starburst

1. INTRODUCTION

Understanding the warm, ionized gas outside of galaxies is a critical aspect of galaxy evolution. To study this gas, there have been two main probes: (1) observations of extraplanar ionized gas in edge-on galaxies (e.g., Rand et al. 1990; Tüllmann et al. 1995; Otte et al. 2001; Miller & Veilleux 2003; Rossa & Dettmar 2003) and (2) low-ionization metal-line absorption studies using quasar sightlines (e.g., Tumlinson et al. 2011; Werk et al. 2013, 2014).

These studies have led to the discovery of diffuse ionized gas (DIG; Hoyle & Ellis 1963; Reynolds 1985), which is a layer of warm, low-density ionized gas that extends out to several kiloparsecs into the halos of galaxies, and the confirmation of the circumgalactic medium (CGM; Bergeron 1986; Lanzetta et al. 1995), which is a gas reservoir containing warm, ionized gas that is of even lower density than the DIG and extends hundreds of kiloparsecs into the halos of galaxies. But how this gas relates to the evolution of their host galaxies is an open question.

In this work, we further our understanding of warm, ionized gas in the halos of galaxies by studying a rare and unusual gas complex in the SDSS-IV MaNGA survey (Bundy et al. 2015). Designed to observe galaxies out to a maximum radius of 2.5 effective radii (R25), the MaNGA survey has observed a dusty, starbursting27 galaxy that is on the upper end of the mass–metallicity relationship (Tremonti et al. 2004) out to 6.3R25 through a fortuitous overestimation...

27 We define starbursts as galaxies with log ΣSFR > −1 M⊙ yr−1 kpc−2 (Kennicutt & Evans 2012).
of $R_e$.\textsuperscript{28} This galaxy shows no signs of interaction and displays a large Hα extension with no optical counterpart in the Sloan Digital Sky Survey Data Release 7 (SDSS DR7; York et al. 2000; Abazajian et al. 2009).

Throughout this work, we assume a flat cosmological model with $H_0 = 70$ km s$^{-1}$ Mpc$^{-1}$, $\Omega_m = 0.30$, and $\Omega_{\Lambda} = 0.70$.

2. DATA

The data used in this work are from the ongoing SDSS-IV MaNGA survey (Bundy et al. 2015; Drory et al. 2015; Law et al. 2015; SDSS Collaboration et al. 2016; Yan et al. 2016), which is an integral field unit (IFU) survey that is taking resolved spectroscopy of 10,000 nearby galaxies with log $M_*/M_\odot \gtrsim 9$. The survey uses the SDSS 2.5 m telescope (Gunn et al. 2006) and BOSS spectrographs (Smee et al. 2013); pilot studies using P-MaNGA data include Li et al. (2015), Wilkinson et al. (2015), and Belfiore et al. (2015). The r-band signal-to-noise ratio (S/N) in the galaxy outskirts is 4–8 Å$^{-1}$, and the wavelength coverage is 3600–10000 Å. The effective spatial resolution is $2.5''$ (FWHM), with an instrumental resolution of $\sigma \approx 60$ km s$^{-1}$ and a spectral resolution of $R \sim 2000$.

The MaNGA sample and data products were drawn from the internal MaNGA Product Launch-4 (MPL-4), which contains 1368 galaxies. Ancillary data are from the MPA-JHU DR7 value-added catalog\textsuperscript{29} and the NASA-Sloan Atlas.\textsuperscript{30}

The stellar masses from the MPA-JHU DR7 value-added catalog are estimated by fitting a large grid of stellar population models from Bruzual & Charlot (2003) to the $ugriz$ SDSS photometry, following the philosophy of Kauffmann et al. (2003) and Salim et al. (2007). The fiber star formation rates from the MPA-JHU DR7 value-added catalog are estimated using the technique described in Brinchmann et al. (2004), where galaxies with emission lines are fitted with the models of Charlot & Longhetti (2001). The fiber star formation rate surface density is calculated over the 3'' diameter SDSS fiber.

The stellar continuum of each spaxel is fit by the MaNGA Data Analysis Pipeline (DAP; K. Westfall et al. 2016, in preparation), which uses pEXP (Cappellari & EMSellem 2004) and the MIUSCAT stellar population models (Vazdekis et al. 2012). Although the MIUSCAT templates are built to reflect simple stellar populations, the mix of templates used to construct the best-fit stellar continuum does not represent a physically motivated stellar population.

Emission-line fluxes are measured through simple flux-summing after subtraction of the stellar continuum (where there is stellar continuum). The wavelength passbands over which they are integrated are similar to that of Yan et al. (2006), ranging from 10 to 20 Å around the central wavelength. For spectra that do not have measured stellar continua, we subtract a baseline continuum that is based on a linear fit to the red and blue sidebands; these sidebands extend approximately 100 Å beyond the central passbands and have been chosen to avoid other strong emission lines.

\textsuperscript{28} MaNGA uses $R_e$ measurements from the NASA-Sloan Atlas, which estimated $R_e = 77.4$ for this galaxy. After masking out the bright, nearby stars, we used GALFIT (Peng et al. 2002) to fit a single Sérsic model to this galaxy, yielding $R_e = 25''$; see Section 2.
\textsuperscript{29} http://www.mpa-garching.mpg.de/SDSS/DR7/
\textsuperscript{30} http://www.nsatlas.org

We adopt the nonparametric quantities $v_{\text{peak}}$ and $W_{80}$ to characterize the center (with respect to the systemic velocity of the host galaxy) and width (that contains 80% of the flux) of the Hα emission line (e.g., Harrison et al. 2014). We only measure $v_{\text{peak}}$ and $W_{80}$ in spaxels where the Hα flux has S/N > 5.

To estimate the gaseous metallicities, $12 + \log(O/H)$, we use the [ZII] code (Blanc et al. 2015), which estimates the ionization parameter and gaseous metallicity based on a Bayesian analysis of a model grid with a set of input line fluxes; we used the Dopita et al. (2013) model grids, but we obtain similar results to those of Levesque et al. (2010). We provide [O II] $\lambda\lambda3727, 3729$, $\lambda\beta$, [O III] $\lambda\lambda5007, H_\alpha$, [N II] $\lambda\lambda6583$, and [S II] $\lambda\lambda6717, 6731$; all provided line fluxes have S/N $> 3$. Throughout this work, we correct for reddening using the Balmer decrement and the Fitzpatrick (1999) extinction law. The typical uncertainties of these [ZII] metallicities are 0.1–0.3 dex.

We also estimate the gaseous metallicity using the [N II]/[O II] calibration from Kewley & Dopita (2002), which is relatively insensitive to variations in ionization parameter and is least sensitive to DIG contamination (Zhang et al. 2016, submitted). We estimate the uncertainties by adding in quadrature the intrinsic scatter of this calibration (0.04 dex; see Kewley & Dopita 2002) and the measurement error of log [N II]/[O II] propagated through the calibration, resulting in typical uncertainties of 0.05–0.15 dex.

3. RESULTS

Our main result is presented in Figure 1. The SDSS gr$^i$ color image of the system is shown in Figure 1(a), with the MaNGA footprint outlined by the magenta hexagon. Figure 1(b) displays the Hα flux map of this system, with the Hα flux contours in light gray. There is a large extension in the Hα flux distribution that extends $\approx 3''$ ($\approx 6.3$ kpc) to the left (east) beyond the effective radius of the host galaxy and does not correspond to any optical source in SDSS. This striking feature is elucidated in Figure 1(c), where we present the Hα flux contours superimposed on the SDSS r-band image, with the blue circle marking the $R_e$ of the host galaxy.

Figures 1(d) and (e) show the spectra centered on the Hα emission line of the highlighted spaxels in the Hα complex (which is 6'' away from the center) and in the center of the host galaxy, respectively. Both spectra possess strong emission from the [N II] doublet, Hα, and the [S II] doublet, confirming the authenticity of this Hα extension and indicating the presence of ionized gas throughout the entire system. Stacking all the spectra within the green circle centered in the Hα extension of Figure 1(b)—which we will refer to as the “Hα circle”—does not reveal a significant continuum. Properties of the host galaxy are listed in Table 1.

Figure 2 presents the gaseous metallicities, $12 + \log(O/H)$, of this system using [ZII] (Figure 2(a)) and the [N II]/[O II] calibration (Figure 2(b)), with the Hα flux contours overlaid and the same spaxels from Figure 1(b) highlighted in white. Using the estimates of [ZII] (the [N II]/[O II] calibration), the stacked $12 + \log(O/H)$ value in a 1'' circle centered on the host galaxy is $9.06 \pm 0.06$ (8.92 ± 0.02), whereas the stacked $12 + \log(O/H)$ value in the Hα circle is $8.81 \pm 0.05$ (8.77 ± 0.03)–0.25 (0.15) dex less than the center of the host galaxy at greater than 99.7% confidence. Comparing these gaseous metallicities to the solar value ($12 + \log(O/H)_{\odot} = 8.69$; Asplund et al. 2009) reveals that the entire
system has supersolar gaseous metallicities (but see Kennicutt et al. 2003 for caveats associated with strong-line abundances).

Figures 2(c) and (d) display the $12 + \log(O/H)$ profile as traced by the highlighted spaxels in Figures 2(a) and (b), with the characteristic metallicity profile of noninteracting disks from Sánchez et al. (2014) overlaid in the dashed line (with an arbitrary zero point). Out to $\sim 2R_e$, the metallicity profiles of this system are similar to that of Sánchez et al. (2014). At $\gtrsim 2R_e$, however, there appears to be a break that corresponds to the location of the H$\alpha$ extension.

The estimated metallicity profile of this system, however, is highly uncertain, as indicated by the large error bars from $\text{[N II]}$, which, unlike the $\text{[N II]}/\text{[O II]}$ calibration, considers multiple strong emission lines (see Section 2). These large error bars from $\text{[N II]}$ likely reflect the contrasting diagnostic line ratios, which may be due to the blending of physically different emission regions caused by insufficient spatial resolution.

Another source of uncertainty is the DIG contribution to the emission-line ratios, which could produce artificial metallicity gradients, especially in the outskirts of the system (K. Zhang et al. 2016, in preparation). While we argue that DIG is not the major component of this system in Section 4.1, we cannot rule out minor DIG contributions that could affect the estimated metallicity gradients of this system.

The ionized gas kinematics of this system is presented in Figure 3, with $v_{\text{peak}}$ displayed in panel (a) and $W_{\text{90}}$ in panel (b); again, we superimpose the H$\alpha$ flux contours and highlight the two spaxels from Figure 1(b). Figure 3(a) reveals an asymmetric gradient that ranges from $v_{\text{peak}} \approx -140$ km s$^{-1}$ at the H$\alpha$ extension to $v_{\text{peak}} \approx 40$ km s$^{-1}$ at the right side of the host galaxy. Figure 3(b) shows typical values of $W_{\text{90}} \approx 230$ km s$^{-1}$, with areas of enhanced $W_{\text{90}}$ in the H$\alpha$ extension and the outer envelope of the H$\alpha$ flux distribution. The velocity profile of the highlighted spaxels in Figure 3(a) is shown in Figure 3(c), with $R_e$ of the host galaxy marked by the vertical dashed lines. $v_{\text{peak}}$ rises smoothly out to $\pm 5''$, where it starts to flatten. Beyond $-5''$, however, there is an irregular wiggle in $v_{\text{peak}}$ that corresponds to boosted $W_{\text{90}}$ in the H$\alpha$ extension.

The $\text{[N II]}$ and $\text{[S II]}$ BPT (Baldwin et al. 1981) diagrams for this system are presented in Figures 4(a) and (b), respectively. We only consider spaxels with emission lines that have

S/N > 3 and overlay curves from Kewley et al. (2006) that are used to separate different classes of galaxies. Figures 4(c) and (d) display the resolved [N II] and [S II] BPT diagrams, respectively, i.e., these maps color-code each spaxel according to its location in their respective BPT diagrams. We overplot the Hα flux contours and highlight the same two spaxels in Figure 1(b). Figure 4 demonstrates that almost all spaxels have HII line ratios.

4. DISCUSSION

In this section, we discuss the nature of the Hα extension.

4.1. Diffuse Ionized Gas

The presence of warm, ionized gas in the outskirts of galaxies has been commonly referred to as DIG (Hoyle & Ellis 1963; Reynolds 1985). The most pronounced characteristics of the DIG are the elevated [N II]/Hα and [S II]/Hα line ratios compared to H II regions (e.g., Monnet 1971; Rand et al. 1990; Rand 1997, 1998; Haffner et al. 1999; Tüllmann et al. 2000; Collins & Rand 2001; Otte et al. 2001, 2002; Hoopes & Walterbos 2003; Wood & Mathis 2004; Voges & Walterbos 2006; Rand et al. 2008; Haffner et al. 2009; Reynolds et al. 2012), which may be due to secondary ionization/heating sources (e.g., Reynolds & Cox 1992; Reynolds et al. 1999). Thus, comparing the line ratios of the Hα extension to that of H II regions would constrain whether the Hα extension is DIG.

Ideally, we would identify individual H II regions in our system in order to conduct this comparison. However, the spatial resolution of the MaNGA data is too coarse—the FWHM is 2′′/5, which corresponds to ≈1.9 kpc at z = 0.038 (the host galaxy’s redshift), which is more than an order of magnitude larger than typical H II regions (1–100 pc; Kennicutt 1984; Hunt & Hirashita 2009). Therefore, every spaxel in our data contains contributions from both H II regions and DIG.

One way to constrain the DIG contribution of the Hα extension is by comparing its line ratios to that of the center of the host galaxy, where the Hα surface brightness is the highest and the DIG contribution is the lowest (Ferguson et al. 1996). However, since line ratios are also dependent on metallicity and ionization parameter (Dopita et al. 2000, 2013; Kewley & Dopita 2002; Kewley et al. 2006)—which are likely to be different at the center compared to the Hα extension—one way to constrain the DIG contribution is to compare the line ratios of the Hα extension to the line ratios of the surrounding regions.

We present this line ratio comparison in Figure 5, all of the panels of which have been corrected for reddening according to Section 2. Figures 5(a)–(c) show the log line ratio maps of [N II]/Hα, [O III]/Hα, and [S II]/Hα, and Figures 5(e)–(f) show the log line ratio maps of [O II]/Hα and [O III]/Hα; the white contours represent the Hα flux distribution. Figure 5(d) displays the [N II]/Hα (filled circles), [O III]/Hα (open triangles), and [S II]/Hα (asterisks) line ratio profiles as traced by the highlighted spaxels in Figures 5(a)–(c), while Figure 5(g) presents the [O II]/Hα (filled stars), [O III]/Hα (open squares), and [S II]/[N II] (open diamonds) line ratio profiles as traced by the highlighted spaxels in Figures 5(e)–(f); the black solid line represents the Hα surface brightness profile over the same highlighted spaxels.

Figure 5 indicates a complicated situation. While Figures 5(d) and (g) show that [N II]/Hα generally decreases with more negative offsets from the center of the galaxy, i.e., toward the direction of the Hα extension, the [S II]/Hα, [O III]/Hα, [O II]/Hα, and [O III]/Hα generally increase along the same direction. These enhancing line ratios toward the Hα extension are consistent with DIG, but the decreasing [N II]/Hα line ratio toward the Hα extension is not consistent with DIG (e.g., Hoopes & Walterbos 2003; Voges & Walterbos 2006; Zhang et al. 2016, submitted). The latter trend is particularly striking since [N II]/Hα is sensitive to the temperature of the gas and has been used to infer that the DIG is about 3000 K hotter than H II regions—a defining characteristic of DIG (Haffner et al. 1999; Madsen et al. 2006; Haffner et al. 2009; Reynolds et al. 2012).

Figure 5(d) also shows that the [N II]/Hα profile displays a dip around an offset of −5″, which corresponds to the location of the Hα extension, while the [S II]/Hα profile and the Hα surface brightness profile display a flattening at the same spot. Since the regions surrounding the Hα extension should have a similar metallicity and ionization parameter, the fact that the Hα extension does not display enhanced [N II]/Hα and [S II]/Hα compared to its surrounding regions indicates that the Hα extension is not dominated by DIG. However, since the S/N is low at the outskirts, the comparison of the line ratios at the center of the Hα extension (at ∼5″) to those at the outermost regions is more uncertain.

Another defining characteristic of DIG is its low density (≈10⁻³ cm⁻³, e.g., Haffner et al. 2009). Hence, another way to constrain the DIG contribution is to probe the gas density of the system with the [S II] λ6717/[S II] λ6731 line ratio (Osterbrock & Ferland 2006). We present the [S II] λ6717/[S II] λ6731 line ratio map in Figure 6(a) (with the Hα contours superimposed and the same spaxels from Figure 1(b).
highlighted in white) and the histogram of the $[\text{S II}] \lambda 6717 / [\text{S II}] \lambda 6731$ line ratios for various regions in Figure 6(b).

The $[\text{S II}] \lambda 6717/[\text{S II}] \lambda 6731$ line ratios of the H$_\alpha$ circle range from 1.0 to 1.6, which corresponds to electron densities, $n_e$, of 500 to $<10^{4}$ cm$^{-3}$, respectively (Proxauf et al. 2014). Even though the leftmost edge of the H$_\alpha$ circle shows electron densities that are less than 10 cm$^{-3}$, that a large area of the H$_\alpha$ extension contains dense gas with $n_e \sim 500$ cm$^{-3}$ strongly indicates that the H$_\alpha$ extension is not dominated by DIG.

4.2. Gas Accretion

Alternatively, the H$_\alpha$ extension could be a sign of gas accretion (Sancisi et al. 2008; Rubin et al. 2012; Bouché et al. 2013, 2016; Sánchez Almeida et al. 2014, 2015), which can manifest through a variety of ways, e.g., cold flows (the properties of this galaxy, log $M_*/M_\odot = 9.77$ and $z = 0.038$, suggest cold flows rather than hot flows; Kereš et al. 2005, 2009b; Dekel & Birmboim 2006; Dekel et al. 2009; Danovich et al. 2015; Stewart et al. 2016), recycled wind material (Shapiro & Field 1976; Bregman 1980; Fraternali & Binney 2008; Oppenheimer & Davé 2008; Kereš et al. 2009a; Oppenheimer et al. 2010; Hopkins et al. 2014), or a gas-rich low-surface-brightness (LSB) dwarf galaxy (e.g., Fischer et al. 2015; Leaman et al. 2015).

The supersolar gaseous metallicities of this H$_\alpha$ extension (see Figure 2), however, are inconsistent with gas accretion through cold flows from the intergalactic medium (IGM) since this type of accreting gas is expected to be very metal-poor (Davé et al. 2011; Joung et al. 2012; van de Voort & Schaye 2012).

The HII line ratios of the H$_\alpha$ extension indicate that star formation is the primary source of ionization (see Figure 4), suggesting that the H$_\alpha$ extension is an accreting gas-rich LSB dwarf galaxy. Assuming that this H$_\alpha$ extension is indeed a LSB...
dwarf galaxy, we estimate a stellar mass upper limit of $M_* \sim 10^7 M_\odot$.

To obtain this limit, we first sum the $g$-band flux of every pixel in the H$\alpha$ circle using SDSS DR7; we multiply this sum by 3 and take it as the upper limit of the $g$-band flux. Selecting SDSS DR7 galaxies at $0.02 < z < 0.04$, we plot their mass-to-light ratios ($M/L$) as a function of rest-frame $g-r$ color using the MPA-JHU stellar masses and galaxy $g$- and $r$-band absolute magnitudes from GIM2D (Simard et al. 2011) and then use the typical $M/L$ of star-forming galaxies ($0.2 < g-r < 0.4$) to estimate the stellar mass upper limit of the H$\alpha$ extension, which yields $M_* \sim 10^7 M_\odot$.

A galaxy with such a low stellar mass, however, is unlikely to have the supersolar gaseous metallicities that are observed in the H$\alpha$ extension (Berg et al. 2012; Jimmy et al. 2015), indicating that the H$\alpha$ complex is probably not an accreting gas-rich LSB dwarf galaxy.

Finally, the enhanced values of $W_{80}$ within the H$\alpha$ extension (see Figure 3(b)) that coincide with an unusual $V_{\text{peak}}$ bump in the velocity profile (at $\sim -7''$ of Figure 3(c)) may suggest the presence of turbulence that could be caused by the interaction between accreting gas and the host galaxy. However, such large values of $W_{80}$ may also be an artifact caused by the coarse resolution of the MaNGA data, which could blend multiple components separated by small velocities and/or small distances. Future higher-resolution data will be needed to discern these possibilities.

Therefore, the gas accretion scenario that best matches the properties of the H$\alpha$ extension is recycled wind material (Oppenheimer & Davé 2008; Kereš et al. 2009a; Oppenheimer et al. 2010; Hopkins et al. 2014), which is predicted to be a critical process in shaping the galaxy stellar mass function at low stellar masses ($< 5 \times 10^7 M_\odot/M_\odot$; Oppenheimer et al. 2010; Hopkins et al. 2014).

4.2.1. Gas Accretion Deficit

If this H$\alpha$ extension is indeed accreting gas, then an interesting application would be toward the gas accretion deficit. To elaborate, Sancisi et al. (2008) combined many nearby H i studies to show that the visible H i gas accretion rate

![Figure 3](image-url)

(a) Peak velocity, $V_{\text{peak}}$ of the system. (b) Line width, $W_{80}$ of the system. (c) Velocity profile of the highlighted spaxels in panel (a), where the color corresponds to the color of the highlighted spaxels. The peak velocity lines mark $R_e$ of the host galaxy, and the error bars are the 1σ uncertainties estimated by resampling the data 1000 times. Panel (c) shows that the H$\alpha$ extension has peak velocities that deviate from regular rotation, arguing against it being part of a skewed disk.
in the local universe is only \( \sim 0.2 \ M_\odot \ yr^{-1} \), which is about an order of magnitude too small to account for the current SFR of local star-forming galaxies (\( \sim 1 \ M_\odot \ yr^{-1} \)). These HI studies, however, only probe cold gas (\( T \lesssim 100 \) K). Simulations predict that most of the gas in cold flows has \( T \gtrsim 10^4 \) K upon entering the host galaxy (Joung et al. 2012; van de Voort & Schaye 2012; Nelson et al. 2013). Thus, probing warm (\( \sim 10^4 \) K), ionized gas from the CGM may alleviate the gas accretion deficit.

To test this idea, we compare the potential warm gas accretion rate onto this galaxy with its SFR. We first calculate the ionized gas mass of the H\( \alpha \) circle using the following equation from Osterbrock & Ferland (2006):

\[
M_{\text{ionized gas}} = \frac{2.82 \times 10^9 \ M_\odot}{L_{\text{H}\beta} (10^{43} \text{ erg s}^{-1}) \left( \frac{n_e}{100 \text{ cm}^{-3}} \right)^{-1}},
\]

where \( L_{\text{H}\beta} \) is the extinction-corrected H\( \beta \) luminosity and \( n_e \) is the electron density. We calculate \( L_{\text{H}\beta} \) by summing the extinction-corrected H\( \beta \) luminosities of every spaxel in the H\( \alpha \) circle, yielding \( L_{\text{H}\beta} = 2.89 \times 10^{39} \text{ erg s}^{-1} \). To estimate \( n_e \), we measure the median [S II] \( \lambda 6717/\lambda 6731 \) ratio (\( \approx 1.3 \); see Figure 6(b)) of the H\( \alpha \) circle to obtain \( n_e \approx 50 \text{ cm}^{-3} \); this calculation yields \( M_{\text{ionized gas}} \approx 1.63 \times 10^6 \ M_\odot \).

The time required for this H\( \alpha \) circle to accrete onto the host galaxy, \( t_{\text{accretion}} \), is estimated by dividing the distance between the H\( \alpha \) circle and the host galaxy with the observed velocity of the H\( \alpha \) circle. This distance, \( \approx 1.5 \times 10^{17} \) km. The median \( v_{\text{peak}} \) of the H\( \alpha \) circle is \( \approx 80 \text{ km s}^{-1} \). Hence, \( t_{\text{accretion}} \approx 6 \times 10^7 \) yr.

Therefore, the average warm gas accretion rate onto the host galaxy is \( M_{\text{ionized gas}}/t_{\text{accretion}} \approx 0.03 \ M_\odot \ yr^{-1} \). If this accreting warm gas were driving the current star formation in the host galaxy, we would expect for this warm gas accretion rate to be similar to the current SFR. However, the estimated star formation rate of the host galaxy is SFR = 1.67 \( M_\odot \ yr^{-1} \), which is almost two orders of magnitude larger than the estimated warm gas accretion rate. Thus, warm gas accretion does not appear to solve the gas accretion deficit for this galaxy.
Figure 5. (a)–(c) The log \([\text{N II}]/\text{H} \alpha\), log \([\text{O III}]/\text{H} \alpha\), and log \([\text{S II}]/\text{H} \alpha\) line ratio maps. (d) Line ratio profiles of \([\text{N II}]/\text{H} \alpha\), \([\text{O III}]/\text{H} \alpha\), and \([\text{S II}]/\text{H} \alpha\) of the highlighted spaxels in panels (a)–(c); the colors correspond to the colors of the highlighted spaxels, and the error bars represent the 1\(\sigma\) measurement error. The black line represents the H\(\alpha\) surface brightness profile across the same highlighted spaxels, with its values indicated by the y-axis on the right side. (e)–(f) The log \([\text{O II}]/\text{H} \alpha\) and log \([\text{O III}]/\text{H} \beta\) line ratio maps. (g) The line ratio profiles of \([\text{O II}]/\text{H} \alpha\), \([\text{O III}]/\text{H} \beta\), and \([\text{S II}]/[\text{N II}]\) of the highlighted spaxels in panels (e)–(f). We only consider spaxels with S/N > 3 for these emission lines and have corrected all these line ratios for reddening.
5. CONCLUSION

In this paper, we present the serendipitous observation of an ionized gas structure that protrudes out of a dusty, starbursting galaxy. Our analysis indicates that this ionized gas complex is most consistent with gas accretion through recycled wind material.

To better understand the nature of this phenomenon, and to constrain the importance of gas accretion through recycled wind material, we need to find more of these extended gas complexes. However, the current MaNGA sample has not observed any other isolated galaxy with an adequately sized integral field unit (≥6.3 R_e) to allow such a search. We hope to address this issue with future MaNGA releases.

We thank Kevin Bundy, Kyle Westfall, and Matthew Bershady for helpful comments and discussions. We also thank the anonymous referee for a constructive report that improved this work.

Finally, the elongated, asymmetric H_\alpha flux distribution of the system (see Figure 1) resembles the morphologies of tadpole galaxies (van den Bergh et al. 1996; Elmegreen et al. 2005, 2007, 2012; Sánchez Almeida et al. 2013; Straughn et al. 2015), suggesting that this H_\alpha extension may be part of a tadpole galaxy. However, in addition to their cometary morphology, another common property of tadpole galaxies is their bright, blue colors that are indicative of recent bursts of intense star formation (Elmegreen & Elmegreen 2010; Elmegreen et al. 2012). Since the H_\alpha extension in our system has no optical or ultraviolet (UV) counterpart, it is unlikely that our system is a tadpole galaxy. Moreover, the supersolar gaseous metallicities of our system are inconsistent with the very metal-poor gaseous metallicities found in local tadpole galaxies (Sánchez Almeida et al. 2013).

4.3. Other Possibilities

Another possibility for this H_\alpha complex is that it is an outflow. If it were an outflow from a starburst, though, we would expect for its 12 + log(O/H) values to be the same as, or higher than, the center of the host galaxy, where the metal-enriching stellar feedback would have likely originated. Instead, we find that the H_\alpha extension has lower 12 + log (O/H), arguing against an outflow. Another possibility is that it is gas disrupted and/or stripped by environmental processes, e.g., mergers or ram pressure stripping (Gunn & Gott 1972). However, since the host galaxy shows no signs of interaction and does not appear to be in a large group, we find this explanation unlikely. Moreover, with a galaxy Sérsic index of n = 3.7, unusual gaseous metallicity profile, and irregular rotation curve, it is also unlikely that this H_\alpha extension is simply part of the host galaxy as a dim, lopsided disk.
