(Received 17 January 2014; published 10 March 2014)

Elastic scattering of photons from $^{12}$C has been investigated using quasimonenergetic tagged photons with energies in the range 65–115 MeV at laboratory angles of 60°, 120°, and 150° at the Tagged-Photon Facility at the MAX IV Laboratory in Lund, Sweden. A phenomenological model was employed to provide an estimate of the sensitivity of the $^{12}$C($\gamma,\gamma')^{12}$C cross section to the bound-nucleon polarizabilities.

I. INTRODUCTION

Much effort has been devoted to studying $\alpha$ and $\beta$, the electromagnetic polarizabilities of the proton and neutron. These polarizabilities represent the first-order responses of the internal structure of the nucleon to an external electric or magnetic field. The majority of nucleon-polarizability measurements have utilized the process of nuclear Compton scattering. A review of these experiments can be found in Ref. [1].

The most recent global fit [1] to all the data up to 170 MeV has yielded polarizabilities for the proton in units of 10$^{-4}$ fm$^3$ of

$$\alpha_p = 10.7 \pm 0.3_{\text{stat}} \pm 0.2_{\text{BSR}} \pm 0.8_{\text{th}}, \quad (1)$$
$$\beta_p = 3.1 \pm 0.3_{\text{stat}} \pm 0.2_{\text{BSR}} \pm 0.8_{\text{th}},$$

where the first uncertainty is statistical, the second is due to uncertainties in the Baldin sum rule (BSR), and the third is due to theoretical uncertainty. The Baldin sum rule is given by [2]

$$\alpha + \beta = \frac{1}{2\pi^2} \int_{0}^{\infty} \frac{\sigma_{\gamma}(\omega) d\omega}{\omega^2}, \quad (2)$$

where $\sigma_{\gamma}(\omega)$ is the total photoabsorption cross section for the nucleon and $\omega_{th}$ is the threshold energy for pion photoproduction. These results were obtained under the constraint of the present-day evaluation [3] of the BSR for the proton which is

$$\alpha_p + \beta_p = 13.8 \pm 0.4. \quad (3)$$

Similarly, the neutron polarizabilities have been extracted from measurements of $^3$H($\gamma,\gamma'H$). They have been determined to be

$$\alpha_n = 11.1 \pm 1.8_{\text{stat}} \pm 0.4_{\text{BSR}} \pm 0.8_{\text{th}}, \quad (4)$$
$$\beta_n = 4.1 \pm 1.8_{\text{stat}} \pm 0.4_{\text{BSR}} \pm 0.8_{\text{th}},$$

preserving the BSR for the neutron [4]

$$\alpha_n + \beta_n = 15.2 \pm 0.4. \quad (5)$$

It is also reasonable to ask whether the nucleon polarizabilities are modified when the proton or neutron is bound in a nucleus and, if so, to what degree. A multitude of Compton-scattering experiments have been carried out with a variety of light nuclei (see Table I) for the purpose of determining the bound-nucleon polarizabilities ($\alpha_{\text{eff}}$ and $\beta_{\text{eff}}$) given by

$$\alpha_{\text{eff}} = \alpha_N + \Delta \alpha, \quad \beta_{\text{eff}} = \beta_N + \Delta \beta, \quad (6)$$

where $\Delta \alpha$ and $\Delta \beta$ are the nucleon-averaged free polarizabilities and $\alpha_N$ and $\beta_N$ represent the nuclear modifications [13] which can be extracted from the scattering data.
These data sets have been analyzed using a model that parameterizes the Compton-scattering amplitude in terms of the electromagnetic polarizabilities. This model is based on the work presented in Ref. [9]. The Compton-scattering amplitude can be written \[ R(E,\theta) = R_1^{SG}(E,\theta) + R_2^{SG}(E,\theta). \] (7)

The first two terms in Eq. (7) are related to the giant resonances (E1, E2, and M1; hereafter referred to as GR) and the quasideuteron (QD) processes, respectively. The amplitudes are given by
\[
R_{GR}(E,\theta) = f_{E1}(E)g_{E1}(\theta) + f_{E2}(E)g_{E2}(\theta)
+ f_{M1}(E)g_{M1}(\theta) + \frac{NZ}{A}r_0[1 + \kappa_{GR}]g_{E1}(\theta),
\] (8)

and
\[
R_{QD}(E,\theta) = \left[ f_{QD}(E) + \frac{NZ}{A}r_0\kappa_{QD} \right]F_2(q)g_{E1}(\theta),
\] (9)

where the complex forward-scattering amplitudes are denoted by \( f_\lambda(E) \) (\( \lambda = E1, E2, M1 \)), the appropriate angular factor is \( g_\lambda(\theta) \) (see Ref. [8] for the angular factors), \( r_0 \) is the classical nucleon radius, and the enhancement factors \([1 + \kappa_{GR}]\) and \( \kappa_{QD} \) are the integrals of the GR and QD photoabsorption cross sections in units of the classical dipole sum rule. Since the QD process is modeled as an interaction with a neutron-proton pair, it is modulated by a two-body form factor \( F_2(q) \) where \( q \) is the momentum transfer.

The seagull amplitudes account for subnucleon and meson-exchange degrees of freedom and are necessary to preserve gauge invariance in the total scattering amplitude. The one-body seagull amplitude is
\[
R_1^{SG}(E,\theta) = \left\{ -Zr_0 + \left( \frac{E}{\hbar c} \right)^2 A_\alpha \right\}g_{E1}(\theta)
+ \left\{ \left( \frac{E}{\hbar c} \right)^2 A_\beta \right\}g_{M1}(\theta) F_1(q),
\] (10)

where the higher-order terms have been omitted. This process is modulated by the one-body form factor \( F_1(q) \) which is given by
\[
F_1(q) = \frac{4\pi}{q} \int_0^\infty \rho(r)\sin(qr)r \, dr,
\] (11)

where \( \rho(r) \) is given by the three-parameter Fermi function [17]
\[
\rho(r) = \rho_0 \frac{1 + \left( \frac{r}{\sigma} \right)^2}{1 + e^{-2(z/r^2)}},
\] (12)

with \( \sigma = 0.149, c = 2.355 \text{ fm}, z = 0.522 \text{ fm}, \) and the form factor is normalized so that \( F_1(0) = 1 \).

The two-body seagull amplitude is
\[
R_2^{SG}(E,\theta) = \left\{ \left( \frac{NZ}{A} \right)^2 \kappa_{QD} + \left( \frac{E}{\hbar c} \right)^2 A_\alpha \right\}g_{E1}(\theta)
+ \left\{ \left( \frac{E}{\hbar c} \right)^2 A_\beta \right\}g_{M1}(\theta) F_2(q),
\] (13)

where the exchange polarizabilities are denoted by \( A_\alpha \) and \( A_\beta \), \( \kappa = \kappa_{GR} + \kappa_{QD} \), and the higher-order terms have been dropped. The two-body form factor is chosen by convention as \( F_2(q) = [F_1(q/2)]^2 \).

The parametrization of the E1 resonance is taken from Ref. [9] where the angle-averaged differential cross section was used to extract the E1 resonance below 40 MeV. The E2 strength between 25 and 35 MeV [12] and an M1 resonance [18] were also included. These included resonances are listed in Table II.

Levinger’s modified quasideuteron model [19] and a damped Lorentzian lineshape were used to define a piecewise function to parametrize the QD process [Eq. (14)]. This parametrization was fit to the existing total photoabsorption cross-section data [20] above 50 MeV in order to establish the normalization. The QD scattering cross section was taken

\begin{table}[h]

tagged photons which struck the target to the number of

\[ \sigma_{\text{QD}}(E) = \begin{cases} \frac{1}{2} \left[ 1 + \tanh \frac{E-E_c}{\Delta E} \right] \mathcal{L}_{\text{QD}}(E), & E < 50 \text{ MeV} \\ L e^{-D/E} \left[ \frac{V}{A} \right] \sigma_D(E), & E > 50 \text{ MeV}, \end{cases} \]

(14)

where \( \sigma_D(E) \) is the deuteron photoabsorption cross section and the parameters \( L = 5.0 \) and \( D = 5.4 \) were determined from the fit to the data. The Lorentzian \( \mathcal{L}_{\text{QD}}(E) \) has the parameters \( E_0, \Gamma, \) and \( \sigma_{\text{QD}} \) given in Table II, with \( E_1 = 40 \) MeV and \( \Delta E = 10 \) MeV. Since the analysis of Warkentin et al. [13] indicated that the extraction of \( \alpha_{\text{eff}} \) and \( \beta_{\text{ef}} \) depends only slightly on the parametrization of the QD amplitude, only the above parametrization will be used in this analysis.

III. EXPERIMENT

The experiment was performed at the Tagged-Photon Facility [21,22] located at the MAX IV Laboratory [23] in Lund, Sweden. A pulse-stretched electron beam [24] with nominal energies of 144 MeV and 165 MeV, a current of 15 nA, and a duty factor of 45% was used to produce quasi-monoenergetic photons in the energy range 65–115 MeV via the bremsstrahlung-tagging technique [25,26]. An overview of the experimental layout is shown in Fig. 1.

The size of the photon beam was defined by a tapered tungsten-alloy primary collimator of 19 mm nominal diameter. The primary collimator was followed by a dipole magnet and a postcollimator which were used to remove any charged particles produced in the primary collimator. The beam spot at the target location was approximately 60 mm in diameter.

The tagging efficiency [26] is the ratio of the number of tagged photons which struck the target to the number of postbremsstrahlung electrons which were registered by the associated focal-plane channel. It was measured absolutely during the experiment startup with three large-volume NaI(Tl) photon spectrometers placed directly in the beam (see below) and it was monitored during the experiment itself on a daily basis using a lead-glass photon detector. The tagging efficiency was determined to be (44 ± 1)% throughout the experiment.

A graphite block 5.22 cm thick was used as a target. The density of the target was measured to be (1.83 ± 0.02) g/cm³. The target was positioned such that the photon beam was perpendicular to the face of the target resulting in a target thickness of (4.80 ± 0.07) × 10²³ nuclei/cm². The average loss of incident photon-beam flux due to absorption in the target was approximately 7%.

Three large-volume, segmented NaI(Tl) detectors labeled BUNI [27], CATS [28], and DIANA [29] in Fig. 1 were used to detect the Compton-scattered photons. The detectors were located at laboratory angles of 60°, 120°, and 150°. These detectors were each composed of a single, large NaI(Tl) crystal surrounded by optically isolated, annular NaI(Tl) segments. The detectors have an energy resolution of better than 2% at energies near 100 MeV. Such resolution is necessary to unambiguously separate elastically scattered photons from those originating from the breakup of deuterium, a parallel and ongoing experimental effort to be reported upon in the near future.

IV. DATA ANALYSIS

A. Yield extraction

The signals from each detector were passed to analog-to-digital converters (ADCs) and time-to-digital converters (TDCs) and the data recorded on an event-by-event basis. The comprehensive dataset presented in this paper was acquired over a five-year period from 2007 to 2012. During this time, the single-hit TDCs used to instrument the tagger focal plane were complemented with multihit TDCs. Data obtained using both types of TDCs are presented here.¹ The ADCs allowed reconstruction of the scattered-photon energies, while the TDCs enabled coincident timing between the NaI(Tl) detectors and the focal-plane hodoscope. The energy calibration of each detector was determined by placing them directly into the photon beam and observing their response as a function of tagged-photon energy. A typical measured in-beam lineshape together with a GEANT4 simulation [32] of the response function of the detector fit to the data is shown in Fig. 2.

Large backgrounds arose when the detectors were moved to the various scattering angles and the beam intensity was increased from 10–100 Hz (for in-beam runs) to 1–4 MHz. Untagged bremsstrahlung photons (related to the beam intensity) and cosmic rays (constant) were the dominant sources of background. An energy cut that accepted only events in the tagged-energy range enabled the prompt peak

¹The interested reader is directed to Refs. [30,31] for a detailed discussion and comparison of the results obtained using the two different types of TDCs.
FIG. 2. Typical in-beam detector response to incident photons as a function of missing energy. The curve is the simulated GEANT4 detector response fit to the data.

[representing coincidences between electrons in the focal-plane hodoscope and events in the NaI(Tl) detectors] to be identified in the focal-plane TDC spectra (see Fig. 3). For each NaI(Tl) detector, events occurring within the prompt peak were selected and a prompt missing-energy (ME) spectrum was filled. ME was defined as the difference between the detected photon energy and the expected photon energy based upon the tagged-electron energy. A second cut was placed on an accidental (or random) timing region and an accidental ME spectrum was filled. This process was carried out for each focal-plane channel.

A net sum ME spectrum for each focal-plane channel was generated by removing both the cosmic-ray and untagged-photon backgrounds. Due to the complex nature of the time structure that exists in the focal-plane TDC spectrum, this process was carried out in two steps. First, the cosmic-ray contribution was subtracted from both the prompt and accidental ME spectra by normalizing these spectra in the energy region above the electron-beam energy. Next, the cosmic-subtracted accidentals were removed from the cosmic-subtracted prompts by normalizing the two spectra in the energy range above the tagged-photon energy corresponding to the particular focal-plane channel but below the electron-beam energy. The focal plane was divided into four energy bins, each approximately 9 MeV wide. The background-corrected ME spectrum for each tagged channel in a particular energy bin was then summed to create a ME spectrum for that bin, such as the one shown in Fig. 4.

A GEANT4 simulation was employed to determine the total yield in the elastic-scattering peak and also to quantify any corrections due to finite geometrical effects. The simulation output was first determined for the case of a NaI(Tl) detector positioned directly in the low-intensity photon beam (θ = 0°) as shown in Fig. 2. This intrinsic simulation was then smeared with a Gaussian function to phenomenologically account for the individual characteristics of each NaI(Tl) detector that are difficult to model in GEANT4. The simulated detector response, with the smearing determined as above, was then fit to the scattering data over the region of interest (ROI) indicated by the vertical dashed lines shown in Fig. 4. The fit GEANT4 lineshape was then used to correct for the detection efficiency of the NaI(Tl) detector in the ROI. This efficiency accounts for events that deposit some energy outside the ROI in the detector. Additionally, the correction factor for photons absorbed by the target and the correction to the detector acceptance due to the finite geometry of the experimental setup were obtained from this simulation.

B. Normalization

The scattering-photon yield was then normalized to the number of photons incident on the target and corrected for rate-dependent factors. The number of photons incident on the target was determined from the number of postbremsstrahlung electrons detected in each focal-plane channel and the
measured tagging efficiency. The rate-dependent corrections included “stolen” trues [33], “missed” trues, and “ghost” events [34]. A stolen true arose when a random electron was detected in the focal-plane channel prior to the electron corresponding to the tagged photon. This correction was only applied to the single-hit TDC data. It was determined using the method outlined in Ref. [35] and was typically 20%–45%. Missed trues resulted from dead-time effects in the focal-plane instrumentation electronics. Ghost events were an artifact of the physical overlap of the focal-plane counters. The missed trues and ghost corrections were determined using a Monte Carlo simulation of the focal-plane electronics and amounted to approximately 5% and 1%, respectively.2

C. Systematic uncertainties

The systematic uncertainties in this experiment were grouped into three types. The first was an overall scale systematic uncertainty that affected the data obtained at all angles and energies equally. This uncertainty arose from normalization factors such as the tagging efficiency. The second type of uncertainty varied only with angle but not energy and was due to the acceptance of the individual NaI(Tl) detectors. This uncertainty had two origins: (1) the distance and aperture size of the detector in its scattering location; and (2) the effect of placing cuts on the data during analysis. Finally, certain uncertainties were strongly dependent on kinematics and varied with both energy and angle such as the stolen-trues correction. The dominant sources of systematic uncertainties are listed in Table III along with typical values. The systematic uncertainties were combined in quadrature to obtain the overall systematic uncertainty.

D. Cross sections

The 12C elastic scattering cross sections measured in this experiment are presented in Table IV. The results are also shown in Fig. 5, along with the results from [10–13] above 55 MeV. The new data are in excellent agreement with the results from Schelhaas et al. [10] and Warkentin et al. [13].

V. RESULTS

The most recent interpretations of 12C(γ,γ) cross-section data [12,13] utilize multiple Lorentzian lineshapes to construct the E1 scattering amplitude. However, in our analysis, the phenomenological model is unable to fit the low-energy data of Wright et al. [9] using these lineshapes (see Fig. 6). In an attempt to incorporate all the published data, we have elected to use the analysis procedure detailed in Ref. [9] where the E1 resonance is deduced from the low-energy (<40 MeV), angle-averaged Compton-scattering cross section, and the QD scattering amplitude is given by Eq. (14). The E2 and M1 resonances below 40 MeV are included for completeness but have little effect on the results.

As suggested by Wright et al. [9] and reinforced by Warkentin et al. [13], we also allowed for the possibility of E2 strength above 50 MeV. A third E2 resonance was added to the phenomenological model (with an equivalent lineshape subtracted from the QD parametrization so as to not affect the total photoabsorption cross section [14]) with a width of 30 MeV. The best fits to the data were achieved with an E2 resonance energy of approximately 90 MeV and a peak strength of approximately 0.2 mb. These values are consistent with the resonance assumed by Warkentin et al. The
addition of this E2 resonance reduced $\chi^2$ by approximately 30% compared to an identical fit without the additional E2 strength.

With the above parametrization, we were able to fit the entire world data set (excluding the data from Häger et al. [12]) below 150 MeV with the phenomenological model. Four different approaches were used involving different combinations of the BSR, the bound-nucleon polarizabilities ($\alpha_{\text{eff}}$ and $\beta_{\text{eff}}$), and the exchange polarizabilities ($\alpha_{\text{ex}}$ and $\beta_{\text{ex}}$) (see Table V). In approach (1), $\alpha_{\text{eff}}$ and $\beta_{\text{eff}}$ were varied under the BSR constraint while $\alpha_{\text{ex}} = \beta_{\text{ex}} = 0$ were fixed. In approach (2), the effective polarizabilities were fixed while the exchange polarizabilities were varied. In approach (3), $\alpha_{\text{ex}} = \beta_{\text{ex}} = 0$ were once again fixed, and $\alpha_{\text{eff}}$ and $\beta_{\text{eff}}$ were varied without the BSR constraint. In approach (4), using only the BSR constraint, all the polarizabilities were allowed to vary in order to minimize the $\chi^2$/DOF. In all four cases, the additional E2 resonance was fixed at $E_{\text{res}} = 89$ MeV, $\sigma_{\text{res}} = 0.22$ mb, and $\Gamma_{\text{res}} = 30$ MeV) as minor variations in the resonance parameters had a negligible effect on the results. Together with the E1 parametrization developed by Wright et al. [12], this analysis presents a consistent framework for fitting the scattering data from photon energies below the giant dipole resonance to energies near the threshold for pion production. The results are summarized in Table V (quantities listed without uncertainties were held fixed during the fitting) and are shown in Fig. 7.

The extracted value of $\alpha_{\text{eff}}$ varied over the range 3–11. Additionally, the exchange polarizabilities were quite large depending on the values used for $\alpha_{\text{eff}}$ and $\beta_{\text{eff}}$. Thus, it is clear that this model for Compton scattering is unable to differentiate between in-medium modifications to the free-nucleon polarizabilities and the effects of the two-body exchange polarizabilities. The results of our analysis indicate that the net electric polarizability of the bound nucleon ($\alpha_{\text{eff}} + \alpha_{\text{ex}}$) is significantly reduced from its free value and that the magnetic polarizability is much larger than its free value. This is in direct opposition to the results reported by Häger et al. [12] where the observed bound-nucleon polarizabilities were in agreement with the free values. The sources of this discrepancy are the reported cross sections, especially at the backward scattering angles (see Fig. 5), and the choice of the model parametrization. Fitting the Häger et al. [12] data alone with the model developed in this paper (with $\alpha_{\text{ex}} = \beta_{\text{ex}} = 0$ fixed) produces a value of $\alpha_{\text{eff}} = 8.2 \pm 0.5$ and $\beta_{\text{eff}} = 6.3 \pm 0.5$. Thus, the

TABLE V. Extracted values of the effective and exchange polarizabilities subject to the constraints outlined in the text.
The effect of a smaller cross section is an increase in the data, especially at the backward angles, are much smaller than those reported in most other experiments \[10,11,13\]. Based on our data and the analysis presented here, we assert that either bound polarizabilities much closer to their free values. Based on the results and analysis, there are in-medium effects and/or exchange polarizabilities that must be accounted for in a full calculation of the Compton-scattering process. Unfortunately, the current world-data set does not indicate which of these effects is more important. The data do seem to have a strong preference for additional \(E2\) strength located above 50 MeV which could be experimentally determined.

**VI. CONCLUSIONS**

In this work, we present a new measurement of the \(^{12}\text{C}\) Compton-scattering cross section for the energy range 65–115 MeV. The results are in good agreement with the previously published results of Schelhaas et al. \[10\], Ludwig et al. \[11\], and Warkentin et al. \[13\]. However, there is a substantial discrepancy with the results reported by Häger et al. \[12\].

The values of the extracted bound-nucleon polarizabilities were found to be strongly dependent on the parametrization of the cross section. The range of extracted \(\alpha_{\text{eff}}\) was 3–11 depending on whether or not the exchange polarizabilities were included. Based on the results and analysis, there are in-medium effects and/or exchange polarizabilities that must be accounted for in a full calculation of the Compton-scattering process. Unfortunately, the current world-data set does not indicate which of these effects is more important. The data do seem to have a strong preference for additional \(E2\) strength located above 50 MeV which could be experimentally determined.

**ACKNOWLEDGMENTS**

The authors acknowledge the outstanding support of the staff of the MAX IV Laboratory which made this experiment successful. We also gratefully acknowledge the Data Management and Software Centre, a Danish contribution to the European Spallation Source ESS AB, for generously providing access to their computations cluster. The Lund group acknowledges the financial support of the Swedish Research Council, the Knut and Alice Wallenberg Foundation, the Crafoord Foundation, the Swedish Institute, the Wenner-Gren Foundation, and the Royal Swedish Academy of Sciences. This work was sponsored in part by the U.S. Department of Energy under Grants No. DE-FG02-95ER40901, No. DE-FG02-99ER41110, and No. DE-FG02-06ER41422, the US National Science Foundation under Award No. 0853760 and the UK Science and Technology Facilities Council.
