ABSTRACT
We present an analysis of the nuclear infrared (IR, 1.6–18 µm) emission of the ultraluminous IR galaxy UGC 5101 to derive the properties of its active galactic nucleus (AGN) and its obscuring material. We use new mid-IR high angular resolution (0.3–0.5 arcsec) imaging using the Si-2 filter (λC = 8.7 µm) and 7.5–13 µm spectroscopy taken with CanariCam (CC) on the 10.4 m Gran Telescopio CANARIAS. We also use archival Hubble Space Telescope/NICMOS and Subaru/COMICS imaging and Spitzer/IRS spectroscopy. We estimate the near- and mid-IR unresolved nuclear emission by modelling the imaging data with GALFIT. We decompose the Spitzer/IRS and CC spectra using a power-law component, which represents the emission due to dust heated by the AGN, and a starburst component, both affected by foreground extinction. We model the resulting unresolved near- and mid-IR, and the starburst subtracted CC spectrum with the CLUMPY torus models of Nenkova et al. The derived geometrical properties of the torus, including the large covering factor and the high foreground extinction needed to reproduce the deep 9.7 µm silicate feature, are consistent with the lack of strong AGN signatures in the optical. We derive an AGN bolometric luminosity Lbol ≈ 1.9 × 1045 erg s−1 that is in good agreement with other estimates in the literature.

Key words: galaxies: active – galaxies: individual: UGC 5101 – galaxies: Seyfert – infrared: galaxies.

1 INTRODUCTION
Ultraluminous infrared galaxies (ULIRGs) are among the most luminous objects in the local universe, with both their luminosities (LIR > 1012 L⊙ emerging mainly in the far-infrared) and space densities being similar to those of quasars (e.g. Sanders & Mirabel...
ULIRGs have large molecular gas concentrations in their central kpc regions (e.g. Downes & Solomon 1998) with densities comparable to those of the stars of elliptical galaxies. For increasing infrared (IR) luminosities, their mid-IR slopes and silicate depths also increase, suggesting that their nuclei are more obscured and more compact (Stierwalt et al. 2013 and references therein). Kormendy & Sanders (1992) proposed that ULIRGs evolve into elliptical galaxies through merger-induced dissipative collapse. In this scenario, these mergers first go through a luminous starburst phase, followed by a dust-shrouded active galactic nucleus (AGN) phase, and finally evolve into an optically bright, naked quasar once they either consume or shed their shells of gas and dust (Sanders et al. 1988a).

The target of interest in this paper is the nearby (z = 0.039; Kim 1995) ULIRG UGC 5101 (IRAS 09320+6134) with a luminosity distance d = 168 Mpc (1 arcsec = 755 pc) for H0 = 73 km s\(^{-1}\)Mpc\(^{-1}\), \(\Omega_m = 0.27\), \(\Omega_{\Lambda} = 0.73\), and an IR luminosity \(L_{\text{IR}} = 10^{12} L_{\odot}\) (Sanders et al. 1988a). In the optical and near-IR the galaxy has a single, very red nucleus within a disturbed morphology, suggestive of a recent interaction and merger (Sanders et al. 1988b; Scoville et al. 2000; Surace, Sanders & Evans 2000).

Optically the AGN has been classified as a Seyfert 1.5 (Sanders et al. 1988a), a LINER (Veilleux et al. 1995), and a Seyfert 2 (Yuan, Kewley & Sanders 2010). Mid-IR spectroscopy taken with ISO (Genzel et al. 1998) as well as ground-based L-band spectroscopy (Imanishi, Dudley & Maloney 2001) demonstrated the presence of a powerful nuclear starburst. Using ground-based high angular resolution mid-IR imaging, Soifer et al. (2000) showed that \(\sim 60\) per cent of the IRAS flux at 12 \(\mu\)m comes from the central 4 arcsec (\(\sim 3\) kpc) and that almost half of this arises in an unresolved core. Based on its IRAS colours, UGC 5101 is classified as a cold, starburst-dominated, far-IR source. However, Chandra and XMM-Newton data detected the Fe-K \(\alpha\) line, which together with the low observed \(L_{\text{Fe-K}}/L_{\text{IR}}\) and \(L_{\text{Fe-K}}/L_{\text{[O III]}}\) ratios likely indicate the presence of a Compton-thick AGN (Imanishi et al. 2003; Ptak et al. 2003; González-Martín et al. 2009). At radio wavelengths, the nucleus of UGC 5101 has a high brightness temperature \((T > 10^3\text{ K})\) with a morphology resembling that of a jet, again pointing to the presence of an AGN (Lonsdale, Smith & Lonsdale 1995; Lonsdale et al. 2003). Using Spitzer IR spectrograph (IRS; Houck et al. 2004) data, Armus et al. (2004, 2007) detected the mid-IR fine structure line of [Ne \(\text{v}\)] at 14.3 \(\mu\)m, which confirms the presence of an AGN in the nucleus of this galaxy.

UGC 5101 offers an ideal scenario for studying the interplay between nuclear activity and star formation in a nearby ULIRG. The \(\sim 5–10\) arcsec spatial resolution of Spitzer/IRS only allowed us to study this interplay in ULIRGs on kpc-scales, although with extremely good sensitivity. For instance, Veilleux et al. (2009) used different indicators on the Spitzer/IRS spectrum of this galaxy and estimated an average IR luminosity, whereas Armus et al. (2007) estimated a 30 per cent contribution from a starburst component.

Here, we present new high spatial resolution (~0.3 arcsec \(\sim 230\) pc) mid-IR imaging and spectroscopy of UGC 5101 obtained with CanariCam (CC; Telesco et al. 2003; Packham et al. 2005) on the 10.4 m Gran Telescopio CANARIAS (GTC). We use these observations to disentangle the unresolved mid-IR emission, which is presumably due to dust heated by the AGN, from that due to star formation in the nuclear region of the host galaxy. By modelling the unresolved near-IR and mid-IR emission with the CLUMPY torus models of Nenkova et al. (2008a,b), we aim to derive the physical and geometrical properties of the obscuring material surrounding the AGN of UGC 5101. The paper is organized as follows.

Section 2 presents the observations and data reduction. In Section 3, we estimate the unresolved emission in the near-IR and mid-IR using the imaging and spectroscopic data. In Section 4, we model the unresolved near and mid-IR emission of UGC 5101 and derive the properties of the AGN and its obscuring material. Section 5 gives the conclusions of this work.

2 OBSERVATIONS AND DATA REDUCTION

2.1 GTC/CC mid-IR imaging and spectroscopy

As part of an ESO/GTC large programme (ID: 182.B-2005, PI: A. Alonso-Herrero) to observe a large sample of local AGN, in 2014 January 6, we observed in queue mode UGC 5101 with CC on the GTC in El Roque de los Muchachos Observatory (La Palma, Spain). CC uses a Raytheon 320 \(\times\) 240 Si:As detector that covers a field of view (FOV) of 26 arcsec \(\times\) 19 arcsec on the sky with a plate scale of 0.0798 arcsec pixel\(^{-1}\). We obtained an imaging observation with the Si-2 filter (\(\lambda_c = 8.7\) \(\mu\)m and width \(\Delta\lambda_{\text{cut}} = 1.1\) \(\mu\)m at 50 per cent cut-on/off) using the standard mid-IR chop-nod technique. The chop and nod throws were 15 arcsec. The airmass during the observation was \(\sim 1.2\). We observed the mid-IR spectrophotometric standard star HD 79354 (Cohen 1999) before the science target. Allowing for overheads, this was 20 min before the science observations. The standard star is used to perform the photometric calibration, estimate the full width half-maximum (FWHM) of the science observation, and perform the point spread function (PSF) subtraction. We measured the FWHM of the data by fitting the radial profile of the standard star with a Gaussian function and obtained a value of 0.4 arcsec. Table 1 summarizes the details of the observations.

We also obtained long-slit mid-IR spectroscopy of the nuclear region of UGC 5101 on the same night. We used the low spectral resolution 10 \(\mu\)m grating, which covers the N-band \(\sim 7.5–13\) \(\mu\)m with a nominal spectral resolution of \(R = \lambda/\Delta\lambda \sim 175\), and a 0.52 arcsec width slit. In Table 1, we list the position angles (PA) of the slit, measured from the north to the east. The observing sequence was as follows. We first took an acquisition image of the galaxy with the Si-2 filter, then centred the slit on the peak mid-IR brightness, and finally integrated for the on-source integration times given in Table 1. We used the same chop-nod parameters as for the imaging observations. We also observed standard stars using the same observing sequence to provide the photometric calibration, the telluric correction, and the slit loss correction. We also used the acquisition image of the standard star to obtain the FWHM of the spectroscopic observation (see Table 1).

Notes. \(N_{\text{obs}}\) is the number of repetitions performed, \(t_{\text{on}}\) is the on-source integration time of UGC 5101 and \(t_{\text{on-STD}}\) is the on-source integration time of the standard star. The FWHM is measured from the image of the standard star. The PA value for imaging is the orientation of the detector on the sky, while for spectroscopy it indicates the orientation of the slit.
We reduced the CC data using the REDCAN pipeline for the reduction and analysis of ground-based mid-IR CC and T-ReCS imaging and spectroscopic data (González-Martín et al. 2013). Briefly, the reduction process of the imaging data includes sky subtraction, stacking of the individual images, and rejection of bad images. The flux calibration of the galaxy image is done using the observation of the standard star. Fig. 1 (left-hand panel) shows the fully reduced 8.7 \( \mu \)m CC image of UGC 5101 together with that of the standard star (middle panel). As also found by Soifer et al. (2000) at 12 \( \mu \)m using the Keck telescope, UGC 5101 is clearly extended in the mid-IR (see Section 3.2).

For the spectroscopy, the first three steps of the data reduction are the same as for the imaging. Additionally, REDCAN performs the two-dimensional wavelength calibration of the target and standard star spectra using sky lines. Then, the trace determination is made using the observation of the standard star. The last steps of the data reduction include the extraction of the spectra either as point sources or extended sources and finally, the correction for slit losses in the case of point source extractions.

### 2.2 Archival HST/NICMOS and Subaru/COMICS imaging

Our target was observed in a single orbit in 1997 November 7 with the Hubble Space Telescope (HST) using camera 2 of NICMOS (Thompson et al. 1998) as part of the Guaranteed Time Observations. This camera uses a 256 \( \times \) 256 HgCdTe array with pixel scales of 0.0762 arcsec and 0.0755 arcsec pixel\(^{-1}\) in and y, respectively, providing a \( \sim \)19.5 arcsec \( \times \) 19.3 arcsec FOV. We use the images of UGC 5101 taken with the broad-band F160W filter (\( \lambda_c = 1.60 \mu m \)) and the medium-band F222M filter (\( \lambda_c = 2.22 \mu m \)). We downloaded the five reduced and calibrated images in each of the F160W and F222M filters from the Mikulski Archive for Space Telescopes (MAST). We combined the individual exposures of each filter using the average of the images. These images were originally presented and analysed in Scoville et al. (2000).

We also downloaded a fully reduced and calibrated image of UGC 5101 taken in the Q-band (\( \lambda_c = 17.7 \mu m \)) from the German Virtual Observatory (GAVO) hosted at the Virtual Observatory (VO). The image was obtained with COMICS on the Subaru Telescope in Mauna Kea, Hawaii. It has an FOV and a pixel scale of 42 arcsec \( \times \) 32 arcsec and 0.13 arcsec pixel\(^{-1}\), respectively. For full details on the Q-band observations and data reduction, we refer the reader to Asmus et al. (2014).

### 2.3 Spitzer/IRS spectroscopy

UGC 5101 was observed with Spitzer/IRS using the short-low (SL) and long-low (LL) modules covering the following spectral ranges: SL1; 7.4–14.5 \( \mu m \), SL2; 5.2–7.7 \( \mu m \), LL1; and 19.5–38.0 \( \mu m \), LL2; 14.0–21.3 \( \mu m \), with a spectral resolution of \( R \sim 60–120 \). The SL slit width is 3.7 arcsec, whereas that of the LL module is 10.5 arcsec. We downloaded the fully calibrated starting mode spectrum from the Cornell Atlas of Spitzer/IRS Source (CASSIS v6; Lebouteiller et al. 2011). CASSIS has identified this object as point-like and therefore it uses its optimal extraction routine to produce the best flux-calibrated spectrum and ensure the best S/N ratio. We stitched the different module spectra together by using the shortest module SL2 flux as reference spectrum for the other modules. The scaling factors were 1.1 for LL1 and LL2.

### 3 Analysis

#### 3.1 Unresolved nuclear emission from the imaging data

Even at high spatial resolutions, in the near-IR up to \( \lambda \sim 2 \mu m \), extended stellar emission arising in the host galaxy contaminates even dominates the nuclear fluxes of AGN, especially in type 2s. At longer wavelengths \( \lambda > 3 \mu m \) contamination by stellar photospheric emission is greatly reduced (Alonso-Herrero et al. 2001 and references therein). Our goal in this section is to use the high angular resolution imaging data to isolate as much as possible the unresolved nuclear emission before we attempt to infer the properties of the obscuring material and the AGN luminosity of UGC 5101 (Section 4). To do so, we need to remove any extended nuclear emission not directly related to the dusty torus and/or emission arising from dust heated by young massive stars (see Alonso-Herrero et al. 2011 and references therein).

Although in the past there have been some attempts to measure the unresolved nuclear emission of UGC 5101 at near- and mid-IR wavelengths (e.g. Scoville et al. 2000; Soifer et al. 2000; Haan et al. 2011; Asmus et al. 2014; Imanishi & Saito 2014), the reported values may still be contaminated by stellar emission and emission due to nuclear star formation. Therefore, we measure the unresolved emission consistently in the archival HST/NICMOS H- and K-band images and COMICS Q-band images as well as in the new CC image. To do so, we use the two-dimensional fitting algorithm GALFIT (Peng et al. 2002) to derive both the unresolved nuclear emission...
and extended emission, as GALFIT allows us to simultaneously fit an arbitrary number of components (e.g. PSF, Sérsic profile, exponential disc, and/or Gaussian functions) to a galaxy image. It is possible, however, that even at these high angular resolutions (0.15–0.40 arcsec) there is still some contamination from other components (stellar emission and star formation, see Section 4).

### 3.1.1 Near-IR emission

To model the unresolved nuclear emission, we generated theoretical Tiny Tim PSFs for the NICMOS camera 2 F160W4 and F222M filters. The Tiny Tim (Krist 1993) PSFs have only three free parameters, namely the central coordinates (x_c and y_c) and the total flux. The total unresolved emission is computed by integrating the flux over the PSF image assuming that it contains 100 per cent of the light. To fit the extended surface brightness distribution, that is, the host galaxy emission, we used a Sérsic profile (see Peng et al. 2002 for more details on profiles).

To constrain the unresolved emission in the near-IR and its uncertainty, we use different combinations of profiles that always include a PSF profile to represent the unresolved emission. These combinations of profiles are: a PSF and a Sérsic profile with all the parameters left to vary freely, a PSF plus a Sérsic profile with fixed $n = 1$, a PSF plus a Sérsic profile with fixed $n = 4$, and finally one PSF plus two Sérsic profiles including a Gaussian profile\(^1\) with all the parameters left to vary freely. We find that the models that include a PSF plus two Sérsic profiles with free parameters and a PSF plus one Sérsic profile with $n = 4$ produce fits with similar $\chi^2 \sim 0.35$ and that the unresolved emission measured on the NICMOS images did not change by more than 1 per cent at both wavelengths. We then conclude that the unresolved component is well constrained at both near-IR wavelengths.

Fig. 2 shows the combined NICMOS 2.22 μm image together with the GALFIT model image and the residual image after subtracting the GALFIT model from the image.

Since the fits with different models are of similar quality, we estimate the uncertainty of the parameters in Table 2 as the standard deviation of the values given by all models. These uncertainties are larger than those estimated for a single model.

The unresolved emission detected in UGC 5101 contributes 2 and 17 per cent of the continuum emission at 1.60 and 2.22 μm, respectively, measured over the HST/NICMOS Camera 2 FOV. Our unresolved fluxes at $H$ and $K$ band are lower than those reported by Scoville et al. (2000) using the same NICMOS/HST images. This is because they only subtracted the underlying galaxy as estimated from the adjacent pixels instead of modelling the host galaxy emission. The $H$-band image was also analysed by Haan et al. (2011)

\(^1\) A Gaussian profile is a special case of the Sérsic profile when $n = 0.5$ and the size parameter is the FWHM instead of $r_{\text{eff}}$. 

---

**Figure 2.** Upper panels: to the left is the combined HST/NICMOS 2.22 μm image (F222M filter) of the nuclear region of UGC 5101, in the middle the GALFIT model image (see Table 2 for the parameters), and to the right the residual image after subtracting the GALFIT model from the original image. The images are shown in a linear scale, rotated so that north is up, east is to the left. The lowest contour is 3σ above the background, with the next contours in 2σ steps. Lower panels: same as upper panels but for the reduced GTC/CC 8.7 μm (Si-2 filter) image. The physical scale of the images is 755 pc arcsec$^{-1}$. 

---

3580 M. Martínez-Paredes et al.
using a similar decomposition technique as used here, where they found similar results for PSF contribution and Sérsic parameters, within the uncertainties. We adopt our own values for the analysis that follows, since our estimation of PSF uncertainties follows the same methodology as that used to measure the unresolved component at K and mid-IR bands, and it considers a larger range of models than in the analysis by Haan et al. The host galaxy parameters are similar to those found in previous studies at both near-IR bands (e.g. Scoville et al. 2000; Haan et al. 2011; Medling et al. 2014).

### 3.1.2 Mid-IR emission

As done for the HST/NICMOS images, we also run GALFIT on the CC 8.7 μm image to estimate the unresolved and integrated emission of the galaxy. For the unresolved component, we used the CC observation of the standard star taken just before the galaxy observation. We assume that the FWHM did not vary on those time-scales and therefore the emission of the standard star can be used to represent the unresolved emission of UGC 5101. We fit a PSF and Sérsic component with all parameters left free to vary. The used to represent the unresolved emission of UGC 5101. We fit a PSF + Sérsic profile model. The best fit had a reduced χ² ≲ 1.5 per cent when compared to the flux in the residual image. After subtracting the GALFIT model, we obtained a residual of less than 1.5 per cent when compared to the flux in the original image. Table 3 lists the unresolved and Sérsic fluxes at 8.7 μm. The unresolved component contributes ∼12 per cent of the observed emission at this wavelength. The uncertainties in the reported profile fluxes are the formal photometric errors reported by GALFIT added quadratically to the standard deviation (6 per cent for both the Sérsic and the PSF components) of the fluxes obtained by considering different convolution box sizes in GALFIT and to the 10 per cent flux calibration uncertainty (see Table 3).

We also estimated the unresolved and integrated emission at 8.7 μm with two independent methods routinely used in the literature for ground-based mid-IR imaging. The first one is referred to as PSF-scaling photometry and is useful only in sources that are dominated by the nuclear emission (see e.g. Mason et al. 2012). This method, we measured the flux within a circular aperture of 0.5-arcsec radius. Next, we scaled the PSF-star image to the centroid of the galaxy emission and measured the flux within the same aperture around the scaled PSF star. This method provides the maximum contribution from an unresolved nuclear source. For UGC 5101, we obtained the integrated emission using a large aperture with a 9.2 arcsec radius, which is the radius at which the curve of growth flattens.

The second method we term PSF-subtraction (e.g. Soifer et al. 2000; Radomski et al. 2002; Levenson et al. 2009; Ramos Almeida et al. 2009,2011; García-Bernete et al. 2014). In this method, we first matched the PSF-star image (see Fig. 1, right-hand panel) to the peak of the galaxy emission, that is, at a 100 per cent level. Then we subtracted the scaled standard PSF-star from the galaxy image at different percentage peak levels until we obtained a flat profile in the residual image at ≤0.3 arcsec. For the CC 8.7 μm image, this was achieved at a subtraction level of 60 per cent of the peak intensity. We then measured the unresolved component by integrating the emission in a 9.2 arcsec-radius aperture on the scaled PSF-star image. We computed the integrated flux by adding the unresolved component to the extended component as measured by integrating the flux in the same aperture radius on the galaxy image after subtracting the scaled PSF image (see Fig. 1, right-hand panel).

We list in Table 3 the unresolved fluxes at 8.7 μm using the PSF-scaling and PSF-subtraction methods. We computed the uncertainties adding in quadrature the photometric error and the uncertainty in the flux calibration (10 per cent). For the PSF-scaling method, we assumed a 6 per cent uncertainty due to time-variability, estimated from the variation in the signal from the standard stars, and a 13 per cent uncertainty due to PSF-variations. These uncertainties are derived in Mason et al. (2012) from several standard stars observed during the same night at mid-IR with T-ReCS and Michelle on the Gemini North telescope. The uncertainties assumed were added in quadrature to the errors previously described. For the PSF-subtraction method we added in quadrature, in addition to all the above error contributions, a 7 per cent of uncertainty due to ambiguity in the best subtraction of the unresolved source. The unresolved fluxes estimated with the PSF methods are in good agreement with the value estimated with GALFIT.

*Notes.* NA = No assigned.
In order to assess the robustness of decomposition and whether there might be a dependency with the adopted PSF, we use the acquisition image of the standard star for spectroscopy obtained 2 h after the science image (see Table 1) and repeat the calculations of \textsc{galfit} decomposition of UGC 5101 with this PSF model. We find an unresolved flux 27 ± 6 mJy, which is consistent with the value derived before. We also find that the Sérsic parameters are consistent with those previously derived and listed in Table 2.

We also used \textsc{galfit} to measure the unresolved flux in the Subaru/COMICS Q-band image at 17.7 μm. In this case, we used a Gaussian profile with a FWHM ∼0.6–0.8 arcsec, which is the range FWHM of the standard star (see Asmus et al. 2014), to represent the unresolved component and a Sérsic profile for the extended component. We considered three Sérsic profiles: one free, one with fixed n = 4, and one with fixed n = 1. The best fit was obtained with a FWHM = 0.65 arcsec for the unresolved component and n = 2.1 ± 1.8. This produced an unresolved flux at 17.7 μm of 158 ± 32 mJy. This is lower than the unresolved flux calculated by Asmus et al. (2014) using the same data set but consistent with that in Soifer et al. (2000) using Keck imaging. The error in the unresolved emission is the quadratic sum of the standard deviation of the flux measured by fitting different profiles and the formal error from \textsc{galfit}.

3.2 Starburst subtracted nuclear emission from the spectroscopic data

Both the \textit{Spitzer}/IRS and the GTC/CC spectra show emission from polycyclic aromatic hydrocarbon (PAH) features (see Figs 4 and 5; and Armus et al. 2004). This indicates the presence of a component due to star formation activity in the regions of ∼393 pc and ∼2.9 kpc probed by CC and IRS, respectively. In Section 4, we will also fit the starburst-subtracted nuclear GTC/CC spectrum to infer the properties of the obscuring material, presumably the dusty torus, around the AGN of UGC 5101. Before we do so, we need to remove the emission due to star formation. Spectral decomposition in the mid-IR has proven to be an efficient method to disentangle the AGN emission from that due to star formation activity in the host galaxy in luminous infrared galaxies (LIRGs), ULIRGs, AGN, and submillimetre galaxies (e.g. Pope et al. 2008; Valiante et al. 2009; Nardini et al. 2010; Mullaney et al. 2011; Alonso-Herrero et al. 2012; Ramos Almeida et al. 2014b; García-Bernete et al. 2015; Hernán-Caballero et al. 2015).

For the spectral decomposition, we used the model proposed by Pope et al. (2008). This model includes three main components: (1) a starburst dominated by the broad features due to PAH molecules up to ∼18 μm (Puget & Leger 1989; Allamandola, Huggins & Sandford 1999), (2) a power-law (or warm blackbody) continuum that represents the obscuring material around the AGN (Genzel et al. 1998), and (3) extinction. The starburst and power-law components can be affected by different degrees of extinction, which is modelled as a foreground dust screen. The model is expressed as

\[ f_\nu = c_1 f_{\nu,\text{PAH}} e^{-c_2 \tau_\text{ext}} + c_3 f_\nu, \]

where \( \tau_\text{ext} \) is the extinction law, \( c_1 \) and \( c_2 \) are the power-law component and starburst extinctions, and \( c_3 \) is the index of the power-law.

Although the use of a power-law continuum in the mid-IR (up to \( \lambda \sim 35 \) μm) is not physically motivated, it represents well the AGN heated dust continuum which usually peaks at \( \lambda \sim 30–50 \) μm (see e.g. Alonso-Herrero et al. 2011).

We used a total of 24 starburst galaxies from the literature including IR-bright galaxies, LIRGs, and ULIRGs (Sturm et al. 2000; Brandl et al. 2006; Rieke et al. 2009; Sargsyan et al. 2011). We used the extinction laws of Chiar & Tielens (2006) for the local interstellar medium (ISM) and the Galactic Center (GC), as they include the absorption due to silicates around 10 and 18 μm. We performed a \( \chi^2 \) minimization and fitted simultaneously the five free parameters \( c_1, c_2, c_3, c_4, \) and \( c_5 \) for each of the starburst templates and extinction laws.

3.2.1 Spectral decomposition of the \textit{Spitzer}/IRS spectrum

Considering that the local ISM extinction law of Chiar & Tielens (2006) covers a range from 1.2 to 27 μm together with the high S/N and spectral range covered by the \textit{Spitzer}/IRS spectrum 5–35 μm compared with the GTC/CC spectrum, we started by decomposing the \textit{Spitzer}/IRS spectrum between 5 and 26 μm. Then, in Section 3.2.2, we use the starburst galaxy obtained from the best \textit{Spitzer}/IRS spectral decomposition fit to perform the spectral decomposition of the nuclear CC spectrum. The best fit for the \textit{Spitzer}/IRS spectrum is achieved using the LIRG ESO 244-G012 spectrum (blue line) from Sargsyan et al. (2011) and a power-law component with an index of \( c_2 = 2.0 \pm 0.2 \) (green line). The index of the power law is similar to that found in the mid-IR for Seyfert 1s and Seyfert 2s (Armir et al. 2007; Ramos Almeida et al. 2009, 2011; Hönig et al. 2010). The fitted power-law component in the mid-IR is consistent with the presence of a hot dust component (\( T > 300 \) K) found by Armus et al. (2007) for this galaxy from the fitting of the infrared spectral energy distribution (SED) of this galaxy.

We also found that the local ISM Chiar & Tielens (2006) extinction law produced a better fit to the data than GC one. As can be seen from Fig. 3, the fit reproduces well the mid-IR emission except for the bluest part of the spectrum. This is due to the presence in UGC 5101 of strong absorption due to water ice under the 6.2 μm PAH feature (see Spoon et al. 2002; Armus et al. 2004), which is not present in the extinction law. Adding the water ice absorption using the laboratory analogues of Gerakines et al. (1995) only improved marginally the fit in this spectral region and the power-law component remained the same.

Table 4 summarizes the relevant parameters of the spectral decomposition of the IRS spectrum. The errors in the derived parameters take into account the 10 per cent uncertainty assumed for the \textit{Spitzer}/IRS spectrum and the standard deviation of the parameters by considering different initial values for the index of the power-law \( c_2 \) (see Section 3.2.2). The starburst-subtracted fluxes (observed, not corrected for extinction) at 8.7 and 12 μm (observed wavelengths) contribute approximately 54 and 50 per cent of the observed emission in the \textit{Spitzer}/IRS spectrum, respectively. The starburst-subtracted fractional contribution at 12 μm is in agreement with that estimated by Hernán-Caballero et al. (2015) using the same IRS spectrum but an independent method. At rest-frame wavelengths longer than approximately 15 μm, the power-law component appears to dominate the continuum emission in the IRS spectrum, although at \( \lambda_{\text{rest}} > 35 \) μm the starburst component has an almost equal contribution. This is also in agreement with the 30 per cent starburst contribution found by Armus et al. (2007) for UGC 5101 using different mid-IR diagnostics.

Using the foreground extinction and silicate optical depth ratio \( A_\lambda/\tau_{\lambda,0.7} = 18 \) from Roche & Aitken (1984) for the local ISM the

Notes. $f_{SBsubs}$ is the flux obtained from subtracting the observed spectrum and the best-fitting starburst model at 8.7 and 12 $\mu$m, respectively.

fitted foreground extinction affecting the power-law component is $A_V = 90 \pm 11$ mag, which is necessary to reproduce the deep 9.7 $\mu$m silicate feature. This high value is also consistent with the presence of dust lanes in the nuclear region, as seen in the HST optical image of this galaxy (Surace et al. 2000).

Finally, we note that using more typical starburst galaxy spectra, like those of Brandl et al. (2006) we obtained similar starburst-subtracted fluxes at 8.7 and 12 $\mu$m, extinctions at 9.7 $\mu$m and power-law index to those obtained with the galaxy ESO 244-G012, although the $\chi^2$ values of the decomposition are larger.

3.2.2 Spectral decomposition of the GTC/CC spectrum

To determine the extraction type of the GTC/CC spectrum (point source versus extended source), we measured the nuclear flux on the CC 8.7 $\mu$m image within a 1 arcsec-diameter circular aperture. We obtained a flux of $57 \pm 5$ mJy (after correction for point source emission). A comparison with the unresolved emission at 8.7 $\mu$m (Table 3) shows that for the CC slit width we can approximate the emission within the slit as a point source. For the extraction as point source, REDCAN uses an extraction aperture that increases with wavelength to account for the decreasing angular resolution. It also performs a correction to account for slit losses. We finally resampled the nuclear CC spectrum to 60 data points to improve the S/N ratio and for later fitting with CLUMPY torus models (Section 4.2). The errors are computed as the quadratic sum of the 10 per cent photometric uncertainty and the rms of the four data point rebinning.

We did the spectral decomposition of the GTC/CC nuclear spectrum as for Spitzer/IRS. However, because of the limited spectral range of the CC spectrum, we fixed the starburst template to the one that provided the best fit to the IRS spectrum (i.e. ESO 244-G012) and used the Chiar & Tielens (2006) extinction law of the local ISM. We found that the best fit with a reduced $\chi^2 = 2.4$ is achieved with an index of the power-law $c_2 = 4.0$. Although this value is consistent with the range of spectral indices found by Buchanan et al. (2006) in a sample of Seyfert 1, 2, LINERs and starburst galaxies, it is larger than that obtained from the Spitzer/IRS decomposition (see Table 4). Therefore, we study the behaviour of the $c_2$ index in the Spitzer/IRS and CC decomposition by comparing the resulting parameters when we vary $c_2$ between 0 and 4. From this analysis, we found that the power-law and starburst extinctions and, the starburst-subtracted fluxes at 8.7 and 12 $\mu$m are well constrained (see Table 4). Thus, we chose to fix the power-law index to $c_2 = 2.0$ for the spectral decomposition of the CC spectrum for consistency. This value agrees well with that derived from the spectral decomposition of the Spitzer/IRS spectrum and those measured in Seyfert 1 and 2 nuclei in the mid-IR (Hönig et al. 2010; Ramos Almeida et al. 2009, 2011).

These results are not highly dependent on the starburst template library adopted. If for instance, we fit the full spectral library of Brandl et al. (2006), we find an equally valid starburst decomposition ($\chi^2 = 3.0$) for NGC1222, and similar values for extinction, and starburst-subtracted fluxes.

We show the best-fitting model (dashed red line and shaded region) to the observed GTC/CC nuclear spectrum (black line and grey shaded region) in Fig. 4, with the green and blue lines showing the individual contributions from the power-law continuum and the starburst components, respectively. As can be seen from this figure, the best-fitting model reproduces well the data and in particular the emission of the 11.3 $\mu$m PAH feature. We therefore subtracted the starburst component from the CC spectrum, so in the next section we can model the starburst-subtracted mid-IR emission.

We list in Table 4 the relevant parameters of the fit to the CC nuclear spectrum. The errors of the parameters are estimated as the standard deviation of the parameters given by different models that fix the value of $c_2$ between 0 and 4. The fitted foreground extinction...
affecting the power-law continuum from the spectral decomposition of the CC nuclear spectrum \( A_V = 115 \pm 36 \) mag is higher than that from the IRS spectrum, although consistent within the uncertainties, possibly indicating that on nuclear scales the heating source is more embedded and the continuum source is extended (see below).

The starburst-subtracted fluxes, not corrected for extinction, at 8.7 and 12 \( \mu \)m (observed wavelengths) from the decomposition of the CC spectrum (see Table 4) contribute approximately 67 and 59 per cent to the nuclear CC spectrum, respectively. Within the uncertainties, these values are in good agreement with those estimated by Hernán-Caballero et al. (2015) for the AGN component. The starburst-subtracted fluxes at 8.7 and 12 \( \mu \)m from the Spitzer/IRS and CC decomposition are consistent with each other, within the uncertainties (see Table 4). In general for nearby Seyfert nuclei, the spectral decomposition of IRS spectra is able to recover both the shape and flux of the AGN component measured from high angular resolution ground-based mid-IR spectroscopy (see e.g. García-Bernete et al. 2014; Hernán-Caballero et al. 2014; Ramos-Almeida et al. 2014b). In the case of UGC 5101, it is more distant than these nearby Seyferts, it is possible that the IRS spectrum has a strong contribution from extended dust components which are more difficult to disentangle from the dust heated by the AGN.

We find, however, that the 8.7 \( \mu \)m starburst-subtracted nuclear flux from the decomposition of the GTC/CC nuclear spectrum is in excellent agreement to within the uncertainties with the unresolved emission derived from the \textsc{galfit} model of the CC imaging data (Section 3.1.2 and Table 3). Soifer et al. (2000) estimated that at observed \( \lambda = 12.5 \) \( \mu \)m, the core component contributed approximately 50 per cent of the flux within a 4 arcsec diameter aperture (\( \sim 185 \pm 10 \) mJy). Within the uncertainties, their inferred unresolved flux is consistent with the starburst-subtracted GTC/CC spectrum at the same wavelength (\( \sim 91 \) mJy) but not with the fitted power-law continuum (see also Fig. 5). This result shows that at this part of the spectrum, the power law is underestimated while the starburst component is well fitted.

4 ESTIMATING THE PROPERTIES OF THE AGN AND THE OBSCURING MATERIAL

4.1 The CLUMPY torus models

The CLUMPY model (Nenkova, Ivezić & Elitzur 2002; Nenkova et al. 2008a,b) holds that the dust surrounding the central engine of an AGN is distributed in clumps. An illustration of this model is shown in Fig. 5. The clumps have a radial distribution \( \propto r^{-\alpha} \) with a radial extent \( Y = R_o/R_d \), where \( R_o \) and \( R_d \) are the outer and inner radius of the toroidal distribution, respectively. The inner radius is defined by the dust sublimation temperature, which is assumed to be \( T_{\text{sub}} \approx 1500 \) K, and the AGN luminosity as \( R_d = 0.4 (1500 \) K \( T_{\text{sub}} \)^{-3/4}(L_{\text{AGN}}/10^{45} \) erg s\(^{-1}\))^\(1/5 \) pc. In this model, each clump has the same optical depth (\( \tau_L \)). The number of clouds along the line of sight (LOS) at a viewing angle \( i \) is \( N_{\text{los}}(i) = N_0 \rho^{-1/4} \tau_{\text{los}}^{-1/2} \), where \( \tau_{\text{los}} \) is the angular width occupied by the cloud distribution and \( N_0 \) is the average number of clouds along a radial equatorial ray. The CLUMPY models have been proven to reproduce the nuclear IR emission of Seyfert galaxies and quasars (see e.g. Mor et al. 2009; Nikutta et al. 2009; Ramos Almeida et al. 2009,2011, 2014a,b; Alonso-Herrero et al. 2011, 2013; Lira et al. 2013; Mori et al. 2014; García-Bernete et al. 2014; Ichikawa et al. 2015; Ruschel-Dutra et al. 2014).

In this work, we use an updated version of \textsc{Bayesclumpy}, a Bayesian tool specifically designed to fit the CLUMPY models to observed SEDs and mid-IR spectroscopy (Asensio Ramos & Ramos Almeida 2009). Within \textsc{Bayesclumpy}, there are two additional parameters not listed in Table 5 that can be fitted or fixed. The first one is the scaling factor called \textit{shift}, which accounts for the vertical displacement needed to match the fluxes of a given model to an observed SED and/or spectrum. This is proportional to the AGN bolometric luminosity. The second one is the foreground extinction \( A_V \) due to the host galaxy which is different from that produced by the torus along the LOS. We use the Chiar & Tielens (2006) extinction law derived for the local ISM, as it provided a better fit to the IRS spectrum (Section 3.2.1). Foreground extinction has been shown to be required to fit the nuclear IR emission of Seyfert nuclei with deep silicate features (see e.g. Alonso-Herrero et al. 2011; González-Martín et al. 2013), as it is the case for UGC 5101. We assume a uniform prior distribution for both of them, with the

Notes: Columns 1, 2 and 3 show the name of the CLUMPY torus model parameters, their symbol and the fitting range. Columns 4 and 5 show the median and MAP values obtained from the posterior distributions.

Figure 6. Left: observed unresolved nuclear SED (red dots) and mid-IR spectroscopy after subtracting the starburst contribution from the CC nuclear spectrum (black dots). The orange dot is the nuclear 880 µm continuum flux from Wilson et al. (2008). We did not use this data point for the BAYESCLUMPY fit (see the text). The blue line and shaded region represent the best CLUMPY torus model and the range of models within the 68 per cent uncertainty in the best-fitted parameters, whereas the solid orange line is the MAP model. Right: enlarged view of the best-fitting CLUMPY torus models (as in the left-hand panel) around the 9.7 and 18 µm silicate features.

foreground extinction being in the range A_V(foreground) = 0–40 mag. BAYESCLUMPY can also incorporate the direct AGN emission to model the data, although in principle there is no clear detection of broad emission lines in UGC 5101 (see the next section).

Under the assumption that the torus models are valid simultaneously for photometric and spectroscopic data and that the noise in all observed data is uncorrelated, the Bayesian approach is insensitive to the fact that there are many more spectroscopic points than photometric ones. This is justified by the fact that the method samples the full posterior distributions and obtains marginalized posteriors for each parameter distribution (Asensio Ramos & Ramos Almeida 2009). The results of the fitting process are the marginal posterior distributions for the six free parameters that describe the CLUMPY dusty torus model plus the vertical shift and foreground extinction.

4.2 Results from the fit to the unresolved SED plus the starburst-subtracted spectroscopy

We modelled the SED and spectroscopy of UGC 5101 using the near- and mid-IR unresolved fluxes plus the starburst-subtracted GTC/CC spectrum. We used as an upper limit the nuclear magnitude in the L band from Imanishi et al. (2014). Both the observed unresolved SED and GTC/CC nuclear starburst-subtracted spectrum of UGC 5101 are plotted in Fig. 6.

</tbody>
</table>

Notes. See equation (2) and (3) for the definition of the covering factors and escape probability.

After fitting the unresolved emission and the starburst-subtracted nuclear spectrum, we obtained the marginal posterior distributions for the six free parameters that describe the CLUMPY dusty torus model (Table 5) plus the vertical shift and foreground extinction A_V. If the observational data contain sufficient information for the fit, then the resulting marginal posterior distributions are centred or show trends at certain values within the considered intervals. From these posterior distributions, we also derived other torus parameters listed in Table 6.

The posterior distributions of the fitted torus model parameters show that they are well constrained (see Fig. 7 and Table 5). Both
the high value of the angular width of the torus \( \sigma_{\text{torus}} \sim 60\% \) and number of clouds along the equatorial direction \( N_0 \sim 12 \) produce high apparent and geometrical covering factors \( f(i) \sim 0.94 \) and \( f_z \sim 0.94 \), which are defined as (see Alonso-Herrero et al. 2011 for details)

\[
f(i) = \frac{L_{\text{torus}}(i)}{L_{\text{host}}(AGN)}
\]

and,

\[
f_z = 1 - \int_0^{\pi/2} P_{\text{esc}}(\beta) \cos(\beta) d\beta.
\]

These high covering factors are consistent with the derived low escape probability for an AGN produced photon \( P_{\text{esc}} \) (see Table 6), which might explain the lack of strong AGN signatures in the optical spectrum of UGC 5101. The fitted angular size and number of clouds along the equatorial direction of the UGC 5101 torus are consistent with the values found for Seyfert 2 nuclei, whereas the torus size of UGC 5101 (\( \sim 35 \) pc) is larger than the typical sizes derived for Seyfert 1 and 2 nuclei using the same modelling techniques (Alonso-Herrero et al. 2011; Ramos Almeida et al. 2011; Ichikawa et al. 2015).

The high value of the foreground extinction, \( A_V = 32^{+6}_{-4} \) mag, is necessary to reproduce the deep 9.7 \( \mu \)m silicate feature observed in the nuclear region. However, compared with the foreground extinctions derived from the Spitzer/IRS and CC spectral decompositions this value is nearly three times lower. This difference can be explained considering that the CLUMPY models include the geometrical properties of the torus and, on this model, the foreground extinction is not the only contributor to the observed deep 9.7 \( \mu \)m silicate feature. The best-fitting models also reproduce well the 17.7 \( \mu \)m unresolved flux around the 18 \( \mu \)m silicate feature. All these values are also consistent with the parameters, including the high covering factors, derived in other LIRGs and ULIRGs hosting deeply embedded AGN, e.g. Arp 299A (Alonso-Herrero et al. 2013), NGC 6240 (Mori et al. 2014), and Mrk 1066 (Ramos Almeida et al. 2014b).

We translated the fitted torus model parameters into two model spectra. The first one corresponds to the maximum-a-posteriori (MAP) values that represent the best fit to the data. The second one is produced with the median values of the probability distributions of the model parameters. We plot these best-fitting CLUMPY models in Fig. 6 together with the both unresolved SED and starburst-subtracted GTC/CC spectrum. We also show in this figure the 880 \( \mu \)m continuum flux of 37 \( \pm \) 9 mJy measured with a 1 arcsec \( \times \) 0.7 arcsec beam (Wilson et al. 2008), although we did not use it for the fit. Clearly, the torus emission is well below this flux, indicating that in the far-IR the nuclear emission is dominated by star formation activity, as already hinted by the spectral decomposition of the IRS spectrum (Section 3.2.1). Additionally, the 880 \( \mu \)m flux may have a significant contribution from non-thermal or radio free–free emission (see discussion by Wilson et al. 2008).

As can be seen from Fig. 6, the best-fitting CLUMPY models reproduce well the shape of the silicate feature and the mid-IR unresolved emission. The 2.2 \( \mu \)m is not well fitted by the CLUMPY models. One possibility is that the near-IR unresolved emission is still contaminated by stellar emission from recent star formation in the nuclear region of the galaxy. However, in this case, the SED of the unresolved emission should be bluer than the observed nuclear \( H - K = 1.9 \) colour derived in this work, and at least two orders of magnitude more luminous than the AGN. Another explanation, more consistent with the nuclear \( H - K \) colour, could be the presence of very hot dust clouds of graphite (\( T \sim 1000 \) K; see for example Mor & Trakhtenbrot 2011). In fact, Alonso-Herrero et al. (2011) found a slight excess at near-IR emission in the modelling of the SED+spectroscopy of some Seyfert 1s and, Mor et al. (2009) also consider a hot dust component for modelling the SED+spectroscopy of a sample of PG quasars.

Thus, may be in UGC 5101, a combination of CLUMPY torus emission+cold foreground absorbing dust screen might not be the appropriate model for active nuclei with very deep silicate features (e.g. Alonso-Herrero et al. 2011; Merlo et al. 2014; Mori et al. 2014) and spherically symmetric smooth models may be more appropriate.
for deeply embedded objects (see Levenson et al. 2007; Alonso-Herrero et al. 2013).

4.3 The AGN luminosity

From the scaling of the fitted CLUMPY models to the data, we derived an AGN bolometric luminosity of $L_{\text{bol}} = (1.9^{+1.5}_{-0.7}) \times 10^{45}$ erg s$^{-1}$. Using the hard X-ray versus 12 µm correlation observed for local Seyfert galaxies (Gandhi et al. 2009; Levenson et al. 2009; Asmus et al. 2011) and the emission contribution by the starburst-subtracted nuclear component at 12µm from the GTC/CC spectral decomposition after correcting for the derived foreground extinction (see Table 4), we predict an intrinsic hard X-ray luminosity $L_{2-10\text{keV}} = (4.1 \pm 0.7) \times 10^{43}$ erg s$^{-1}$. Applying a bolometric correction $[10-20] \times L_{2-10\text{keV}}$ (Marconi et al. 2004), we found a bolometric luminosity between $4.1 \times 10^{43} \leq L_{\text{bol}} \leq 8.2 \times 10^{44}$ erg s$^{-1}$. This range of AGN bolometric luminosities is lower than our estimate from the CLUMPY torus model fit to the unresolved nuclear IR emission and the starburst-subtracted nuclear CC spectrum of UGC 5101.

González-Martín et al. (2009) on the other hand, estimated an X-ray luminosity $L_{2-10\text{keV}} = 7 \times 10^{43}$ erg s$^{-1}$ after applying a Compton-thick correction to the observed 2–10 keV emission. If we consider the above bolometric correction, then the AGN bolometric luminosity is consistent with the value derived from fitting the CLUMPY torus models to the unresolved IR emission and starburst-subtracted nuclear CC spectrum with that predicted from the hard X-ray versus 12 µm correlation.

The inferred AGN bolometric luminosity from the CLUMPY torus modelling accounts approximately for ~56 per cent of the IR luminosity of the system, which is determined using the fluxes in all four IRAS bands (12, 25, 60 and 100 µm) and the flux–luminosity correlation in Sanders & Mirabel (1996). Considering the uncertainties in the AGN bolometric luminosity (see Table 6), this value is consistent with other estimates in the literature. For instance, Lonsdale et al. (2003) using high angular resolution radio observations estimated a 30 per cent AGN contribution in UGC 5101. Veilleux et al. (2009) derived a similar value (35 per cent) using a number of spectral mid-IR diagnostics using the Spitzer/IRS spectroscopy.

In summary, despite the fact that the CLUMPY models do not fit simultaneously all the near- and mid-IR unresolved emission, and starburst-subtracted nuclear CC spectrum of UGC 5101, the derived AGN bolometric luminosity is consistent with estimates using other methods. In our modelling, the AGN bolometric luminosity is only a function of the scaling factor of the models to the data, which is driven mostly by the fluxes near the peak of the torus emission. In the case of UGC 5101, the peak of the best-fitting CLUMPY torus model is at $\lambda_{\text{peak}} \sim 40–50$ µm (see Fig. 6, left-hand panel) and the Q-band data point (observed 17.7 µm) is the closest to that peak. Therefore even for deeply embedded AGN, the modelling of the unresolved nuclear emission and the starburst-subtracted spectroscopy with the CLUMPY torus models can still be useful for deriving the AGN bolometric luminosity, as this quantity is driven by the scaling of the model and is less subject to the detailed modelling of the near and mid-IR SED and the silicate feature.

5 SUMMARY AND CONCLUSIONS

We have presented new high angular resolution (0.3–0.4 arcsec) 8.7 µm mid-IR imaging and 7.5–13 µm spectroscopy of the nuclear region of the ULIRG UGC 5101 using CC on the GTC. We also analysed archival HST NICMOS near-IR and Subaru/COMICS Q-band imaging and Spitzer/IRS spectroscopy. The presence of PAH emission in the nuclear (central ~393 pc) CC spectrum indicates that some of the dust in central region is being heated by the UV radiation of relatively young stars. Therefore, to study the physical and geometrical properties of the obscuring material surrounding the AGN of UGC 5101, it was necessary to disentangle the IR emission presumably due to dust heated by the AGN from that due to nuclear star formation and/or stellar emission.

By using GALFIT, we were able to separate the unresolved nuclear emission from the extended host galaxy emission using the near-IR (1.60 and 2.22 µm) and mid-IR (8.7 and 17.7 µm) imaging data. We also calculated the unresolved emission at 8.7 µm with other methods, namely PSF-subtraction and PSF-scaling and found that the resulting fluxes were similar to those derived with GALFIT. In addition, we found that the Sérsic parameters, which represent the extended emission, derived at near- and mid-IR wavelengths are consistent with each other.

For the mid-IR spectroscopy, we used a spectral decomposition method to estimate the emission of the obscuring material around the AGN, which we represented as an extinguished power-law continuum. We also allowed both components to have different foreground extinctions. From the spectral decomposition of the IRS data, we found an index of the power law ($c_2 = 2.0 \pm 0.2$) consistent with the values observed for Seyfert 1 and Seyfert 2 nuclei (Ramos Almeida et al. 2011). Given the limited spectral range of the CC spectrum for the decomposition, we fixed the index of the power law and starburst template to those derived for the IRS data. Within the uncertainties, the starburst-subtracted nuclear fluxes at 8.7 and 12 µm CC continuum component are consistent with those derived from the spectral decomposition of the IRS spectrum. In addition, the starburst-subtracted nuclear flux at 8.7 µm is also consistent within the uncertainties with the value derived with the GALFIT modelling of the CC imaging data. We also estimated that in the central 393 pc of UGC 5101 the power-law component at 8.7 and 12 µm (observed wavelengths) contributes 67 and 59 per cent of the nuclear emission, respectively.

Before fitting the unresolved SED of UGC 5101 with the CLUMPY torus models of Nenkova et al. (2008a,b), we subtracted the fitted starburst component from the GTC/CC nuclear observed spectrum. We found that CLUMPY torus models with a high covering factor and a high foreground extinction ($A_V \sim 32$ mag) fit well the silicate feature and unresolved mid-IR emission. The high value of the foreground extinction is similar to results for other deeply embedded AGN in local LIRGs and ULIRGs (see e.g. Alonso-Herrero et al. 2013; Mori et al. 2014). However, the observed unresolved near-IR emission of UGC 5101 is well above the fitted CLUMPY models. This could be due to contamination by nuclear stellar emission even at the angular resolution of 0.15 arcsec of the NICMOS data or more likely due to the presence of hot dust clouds. We also showed that the observed 880 µm nuclear flux is much higher than the extrapolation to the far-IR of the fitted torus models. Again, this indicates that there is strong nuclear star formation, as also indicated by the presence of PAH emission in the CC spectrum, and this component also dominates the far-IR nuclear emission of UGC 5101.

Even though the CLUMPY torus models are not able to reproduce simultaneously the nuclear unresolved near and mid-IR emission, and the starburst-subtracted GTC/CC nuclear spectrum of UGC 5101, the derived AGN bolometric luminosity ($L_{\text{bol}} \sim 1.9 \times 10^{45}$ erg s$^{-1}$) is consistent with that estimated from hard X-rays.
